Keywords

Metabolism
The chemical processes that occur within a living organism in order to maintain life; the interconnected sequences of mostly enzyme-catalyzed chemical reactions by which a cell, tissue, organ, etc., sustains energy production, and synthesizes and breaks down complex molecules.

Lipids
Any of the large group of fats and fatlike compounds which occur in living organisms and are characteristically soluble in certain organic solvents but only sparingly soluble in water.

Fatty Acids
Long-chain aliphatic compounds that contain a carboxylic acid group.

Gene Expression
The process by which a gene's coded information is converted into the structures present and operating in the cell. Expressed genes include those that are transcribed into mRNA and then translated into protein and those that are transcribed into RNA but not translated into protein (e.g., transfer and ribosomal RNAs).

Transcription Factors
The DNA binding proteins that carry out the organic process whereby the DNA sequence in a a gene is copied into mRNA.

Nuclear Receptors
Transcription factors that are activated by the binding of specific ligans that are usually lipid soluble, such as fatty acids or steroids.

Adipose Tissue
Body tissue which is able to store high amounts of neutral fats.

Adipocytes
The cell type found in adipose tissue that is specialized for storage of neutral lipids.

The adipocyte, or fat cell, is a unique, highly specialized cell whose primary function is to provide a depot for storage of excess fat, derived mainly from the diet, which can be mobilized and distributed to other tissues as dictated by the energetic demands of the organism. Although long thought of as a simple passive storage depot for dietary lipid, it is now clear that adipose tissue plays a very active role in regulating energy balance and not only stores and secretes lipid as needed, but also produces hormonal signals that have multiple effects on energy metabolism in many tissue

and organs throughout the body. This new view of adipose tissue (and the adipocyte) as a key regulator of fuel metabolism and partitioning has dramatically increased the interest in the role that this tissue plays not only in normal physiology but also in the etiology and treatment of important metabolic diseases such as diabetes and obesity.

1 Introduction – Adipocytes and the Regulation of Metabolism

Although the physiology of adipose tissue and the molecular and cellular biology of the adipocyte have been subjects of research interest for many years, new work in this area has transformed our understanding of the adipocyte and its role in regulating human physiology. We now recognize that in addition to its long appreciated function as a lipid storage depot, the adipocyte plays a much more active role in regulating whole body fuel partitioning and metabolism. The growing interest in the physiology of adipose tissue and the role that it plays in metabolic regulation is fueled to a large degree by the realization that we are in the midst of a growing epidemic of the metabolic disorders of diabetes and obesity. In most developed countries, the incidence of both of these diseases has increased dramatically in the past few decades. Currently (as of 2003), there are 16 million diabetics in the United States, and the incidence of the disease has increased by 49% from 1990 to 2000, with projections indicating a 165% increase by 2050. There has also been a dramatic increase in the incidence of obesity, with over one-third of the population in the United States now classified as obese. Although the causal relationship between diabetes and obesity is not fully understood, a likely common link is the adipocyte.

In healthy individuals, excess fat is stored in adipocytes while only low amounts of triglyceride are maintained in nonadipocytes. It is thought that in obese individuals, the capacity for adipose tissue to accommodate excess lipid is exceeded, resulting in the abnormal accumulation of lipid in other tissues. This elevation in intracellular triglyceride content has been associated with physiological dysfunction (lipotoxicity) that contributes to the development of obesity-related type 2 diabetes. This pathological accumulation of lipid in nonadipose tissue may be the result of a physiological dysfunction of the adipocyte that is induced by the obese state. In this chapter, we will review the current state of knowledge about fat cell lipid metabolism, and how adipocytes function to balance lipid storage and mobilization to meet the energetic demands of the organism without exposing nonadipose tissues to deleterious fat accumulation.

In addition to its function as an energy-storage depot, we now understand that adipose tissue is also a bona fide endocrine organ, secreting hormones that regulate fat metabolism in other tissues throughout the body. The list of biologically active peptides known to be secreted by fat cells has grown significantly in recent years, and although the physiological function of most of these adipocyte-derived hormones (adipokines) is not fully understood, it is clear that they are important components of the physiological system

that controls lipid storage, distribution, and utilization throughout the body. Our current knowledge of the regulation of adipokine production and their downstream metabolic effects is reviewed below.

Our increased understanding of the active role that adipocytes play in regulating metabolism has stimulated a growing interest in adipose tissue as a therapeutic target for new agents to treat diabetes, obesity, and other metabolic diseases. The underlying assumption for this effort is that drugs acting on adipocyte lipid metabolism parameters or on hormone production pathways could have beneficial effects on metabolic abnormalities of diabetes and obesity. In support of this possibility are recent findings, which are reviewed below, demonstrating that an important family of antidiabetic drugs acts, at least in part, by modulating adipocyte physiology. A complete understanding of the medical significance of the adipocyte will require a comprehensive knowledge of the development of adipocytes and adipose tissue, of molecular biology and physiology of mature adipocyte, as well as the interaction of adipose tissue with the broader regulatory systems that control the whole body energy balance and fuel partitioning.

2
Physiology of the Adipocyte

Perhaps the most well-established function of adipose tissue in man is as a reservoir for the storage and mobilization of energy. Cells of the body utilize energy continuously, yet fuel is obtained from external sources intermittently. Thus, animals have a need to be able to efficiently store energy when food is available and access that energy during periods of fasting. Adipose tissue is highly specialized for the storage of lipid energy in the form of triglycerides and the mobilization of that energy in the form of free fatty acids. Of the energy substrates utilized by tissues, lipid is most efficiently stored and provides greater than twice the energy per gram than either carbohydrate (glycogen) or protein. The significance of this energy reserve is readily appreciated when considering that a man of normal body weight (70 kg, 10% body fat) can survive 40 days on energy reserves stored in adipose tissue.

2.1
Absorption and Storage of Circulating Lipid

Energy is stored in adipocytes in the form of triglycerides and is mainly derived from dietary fat, and *de novo* biogenesis from liver and within adipose tissue. Although human adipose tissue is capable of synthesizing lipid *de novo*, most triglycerides that accumulate in the tissue are derived directly or indirectly from dietary fat. Dietary fat is digested in the gut and repackaged as chylomicrons that are delivered to the systemic circulation via the lymphatics. The liver also plays a major role in the production and packaging of lipids in the form of various lipoproteins that are targeted for utilization in various target tissues, including adipose tissue.

A major mechanism for clearing chylomicrons and very low density lipoproteins (VLDL) from the circulation is through the action of lipoprotein lipase (LPL). As mentioned above, adipocytes express LPL, which is released and targeted to the capillary endothelium (Fig. 1). There, LPL acts on circulating chylomicrons and VLDL, hydrolyzing the neutral lipid core and releasing free fatty acids. The free fatty acids that are released can cross cell membranes and enter

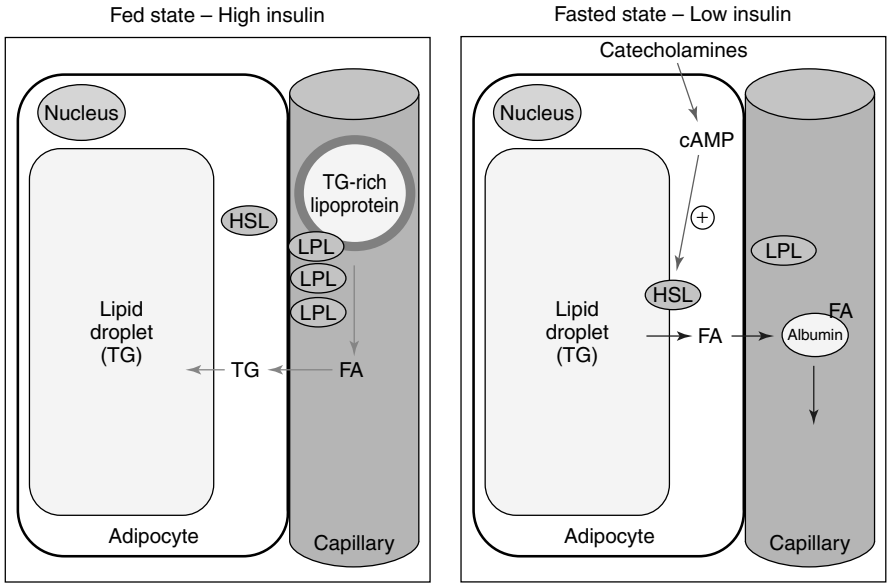

Fig. 1 Lipid storage and mobilization in adipocytes during fed and fasted states. See text for details. Flux of dietary lipid from circulating lipoprotein particles to the adipocyte lipid droplet is shown in green. Flux of stored lipid from adipocyte back into circulation shown in blue. TG, triglyceride; FA, fatty acid; HSL, hormone-sensitive lipase; LPL, lipoprotein lipase. (See color plate p. xxii).

adipocytes directly. Additionally, fatty acids can enter adipocytes via transport proteins, such as CD36 and FATP1. The flow of free fatty acids is governed by its concentration gradient. In the case of adipocytes, free fatty acid (FFA) that enter cells quickly encounter proteins that bind FFA, such as members of the fatty acid binding protein (FABP) family involved in cytoplasmic transport, or enzymes involved in metabolic conversion into triglyceride, such as long chain acyl-CoA synthase, thereby maintaining a significant concentration gradient.

2.2 Mobilization and Release of Stored Lipid into the Circulation

Triglycerides are typically stored within the adipocyte as a single lipid droplet. Recent work indicates that the lipid droplet is an extension of the endoplasmic reticulum surrounded by a single phospholipid layer. Closely associated with the lipid droplet are ''coat proteins'', especially perilipin isoforms and caveolin 2. Perilipin is the most abundant target for phosphorylation by cyclic AMP-dependent protein kinase (PK) in fat cells, and plays a key role in the retention and mobilization of energy from lipid droplets. The energy contained in the droplet is liberated when the triglyceride is hydrolyzed into free fatty acids and glycerol. The rate-limiting step in this process is the activity of hormone-sensitive lipase (HSL) at the surface of the lipid droplet. Although several protein kinases can influence lipolytic rate, the most significant of these is cyclic AMP-dependent protein kinase (PKA). Overall, the rate of lipolysis is

closely governed by the phosphorylation state of perilipin and HSL. Recent work indicates that phosphorylation of perilipin on multiple residues allows recruitment of phosphorylated HSL to the surface of the lipid droplet where triglyceride hydrolysis can take place. Phosphorylation of HSL has only a modest effect on the activity of the enzyme; rather, the dramatic increase in lipolysis produced by PKA-activation reflects the translocation and accessibility of the enzyme to its substrate within the cell. HSL appears to be physically associated with the cytosolic FABP4 (aP2). The significance of this association is not known, but could involve regulation of HSL activity or efflux of mobilized fatty acids. In this regard, mice lacking FABP4 show reduced rates of lipolysis.

Efflux of fatty acids from the fat cell and their transport across the capillary endothelium are thought to occur through passive diffusion across a concentration gradient, although this process has not been studied in detail. Long-chain fatty acids are essentially insoluble in aqueous solution and thus rely on carrier proteins for transport. In plasma, fatty acids are immediately bound with high affinity to serum albumin, which serves as a carrier of these substrates to the sites of oxidation. During fasting, mobilized fatty acids are quickly removed from the circulation, with a half-life of about two minutes, and provide an important source of energy for heart and skeletal muscle.

2.3 Regulatory Mechanisms that Balance Lipid Storage and Utilization

The pathways that promote FFA uptake and esterification to triglyceride are strongly regulated by hormones, particularly insulin. Insulin strongly promotes the synthesis of LPL whose expression coincides with the peak of triglyceride absorption. Insulin and chylomicrons also stimulate the secretion of acylation stimulation protein – a protein made by adipocytes that strongly promotes triglyceride synthesis. Insulin also promotes *de novo* fatty acid synthesis from glucose by stimulating glucose uptake and the expression of lipogenic enzymes.

Fatty acids, derived from adipose tissues, are an important energy source during fasting, exercise, and stress. As mentioned above, the overall rate of lipolysis is largely governed by the relative activation of PKA. The activity of PKA is governed by cAMP levels, which in turn are controlled by receptors coupled positively (beta adrenergic, glucagon, ACTH) or negatively (adenosine, niacin, alpha2, adrenergic) to adenylyl cyclase. In addition, insulin regulates adipocyte cAMP levels by activating phosphodiesterase PDE3b that degrades cAMP. The nature of the pathways controlling lipolysis depends on physiological circumstances. Lipolysis, in response to stress and exercise, is highly dependent on the activity of the sympathetic innervation of adipose tissue as well as the release of epinephrine from the adrenal gland. During fasting, lipolysis does not depend on neural activity, but rather appears to result from decline in insulin that provides tonic activation of PDE3b.

2.4 Adipose Tissue as an Endocrine Organ

As described above, the primary metabolic role of the adipocyte is to absorb and store excess lipid in the form of triglyceride, and to make it available to other tissues in the body as energy needs dictate, by measured release of fatty acids into the circulation. Proper functioning of

Tab. 1 Metabolically active proteins secreted by adipocytes.

Protein/hormone	***Physiological effects***
Leptin	Appetite, autonomic nervous activity
Adiponectin	Insulin sensitivity, fatty acid oxidation
Resistin	Insulin sensitivity
TNF-α	Insulin sensitivity, adipocyte differentiation, inflammation
ANG II	Lipogenesis, blood pressure
ASP	Lipogenesis
IGF	Lipogenesis, adipocyte differentiation
Interleukin-6	Lipolysis in adipocytes, inflammation
Kinins	Insulin sensitivity, tissue remodeling
PAI-1	Insulin sensitivity, blood clotting, atherosclerosis
TGF-β	Lipolysis, angiogenesis

Notes: ANG: angiotensin; ASP: acylation-stimulating protein; IGF: insulin-like growth factor; PAI-1: plasminogen activator inhibitor; TNF: tumor necrosis factor; TGF: transforming growth factor. Table adapted from Schling, P., Loffler, G. (2002) Cross talk between adipose tissue cells: impact on pathophysiology, *News Physiol. Sci.* **17**, 99–104.

this system requires communication between adipose tissue and essentially all the organ systems in the body. In addition to the hormonal and neural signals that regulate lipid uptake and storage, or induce lipolysis and release of fatty acids into the circulation during a fast (discussed above), there are signals that originate in adipose tissue that act to modify various physiological activities in tissues and organs throughout the body. For example, to insure that dietary intake is sufficient to maintain an adequate level of adiposity, there must be communication between adipose tissue and the centers in the brain that control appetite. Likewise, there is communication between adipose tissue and the organs, and the tissues that utilize fat for energy to insure that fatty acid delivered to nonadipose tissues, such as muscle and liver, are handled properly and do not accumulate to abnormal levels. One of the major advances in metabolic research in the last few years has been the discovery that adipocytes secrete hormones that act at specific sites in the body and have important effects on many aspects of energy metabolism. This new understanding of adipose tissue as an endocrine organ has dramatically changed our understanding of the significance of adipocytes in the regulation of metabolism. It is now believed that the adipose-derived hormones (referred to as adipokines) are important components of the integrated system of hormonal and neural signaling pathways that function to regulate the storage and use of metabolic energy. The following is a brief summary of the biology of four of the adipokines that have relatively clear effects on metabolism. Table 1 presents a more complete list of hormone like proteins produced by adipocytes.

The seminal contribution to the concept that adipose tissue produces hormones with important metabolic effects was made by Friedman and colleagues in 1994. These investigators identified the protein product of the *obese* (*ob*) gene that causes

severe obesity in mice when mutated. Leptin is secreted from adipose tissue and regulates body weight by acting directly in the CNS to inhibit feeding behavior. The control of leptin synthesis and secretion is still poorly understood. In general, leptin production and secretion are promoted under conditions of positive energy balance (fed state, high insulin) and suppressed by conditions of net energy deficit (e.g. fasting, catabolic hormone stimulation). As such, plasma leptin levels correlate strongly with total adipose tissue mass, and thereby provide an integrated, long-term signal indicating the status of lipid reserves. The actions of leptin are mediated through specific cell surface receptors, which are located in key central and peripheral target cells. Activation of leptin receptors in diverse brain regions signal a state of positive energy balance. Leptin-sensitive neural systems regulate the activity of the autonomic nervous system involved in energy storage and mobilization, feeding behavior, reproductive physiology, and sexual behavior. Leptin may also have direct effects on energy metabolism in peripheral tissues such as muscle, where it has been reported to cause an increase in fatty acid oxidation rates. Although leptin behaves as an antiobesity hormone in certain animal models, common human obesity does not appear to be due to abnormally low leptin levels.

Another recently identified adipocyte-secreted hormone that may play a role in both obesity and diabetes is adiponectin (also called ACRP30 or adipoQ). Originally identified as a secreted fat-specific protein whose expression was induced following adipogenesis, adiponectin levels were found to be reduced in obesity and increased by weight loss. In addition, the *adiponectin* gene maps to a region on chromosome 3 that is associated with diabetes and metabolic syndrome. Treatment of rodents with adiponectin was found to increase muscle fatty acid oxidation, reverse insulin resistance and improve hepatic insulin action. Together, these observations suggest that the physiological role of adiponectin may be to promote lipid oxidation in nonadipose tissues; in essence it may be a signal from fat indicating to the rest of the body that lipid energy is available and should be used.

In contrast to adiponectin, an adipokine that has recently been identified called *resistin* appears to have diabetes-promoting effects on metabolism. While adiponectin clearly promotes fatty acid oxidation and appears to have insulin-sensitizing effects throughout the body, resistin (also known as adipocyte secreted factor, ADSF or FIZZ3) was found to be over-expressed in rodent models of diet-induced obesity and to induce insulin resistance and glucose intolerance in normal mice. These data suggest that resistin acts in a converse manner to adiponectin, increasing insulin resistance and promoting the development of diabetes. However, this relationship between resistin and diabetes was not observed in all models of the disease and additional work will need to be carried out to fully clarify the role of resistin as another potential link between obesity and diabetes. Another potentially prodiabetic adipokine is the inflammatory cytokine tumor necrosis factor alpha (TNFα), which is secreted by adipocytes under some circumstances. TNFα production by adipocytes is elevated in obese rodents and humans and positively correlates with insulin resistance and in some studies inactivation of TNFα using antibody treatment improved insulin action. As with resistin, the combination of elevated expression in obesity

and insulin resistance promoting activity of these adipokines raises the possibility that it contributes to the functional link between obesity and diabetes. Although a great deal more work needs to be done in this area before we can fully appreciate the multiple roles that adipokine hormones play in the regulation of metabolism, it is clear that they are a crucial component of the physiological system that regulates energy balance and fuel partitioning.

3 Developmental Origin of Adipocytes

3.1 Adipose Tissue Development and Plasticity

The basic functional unit of adipose tissue is the adipocyte. Nevertheless, adipose tissue is complex and contains several cell types in addition to adipocytes, such as endothelial cells, interstitial cells, undifferentiated mesenchymal cells, pericytes, and "very small adipocytes". Indeed, adipocytes constitute less than 20% of the cells residing in typical adult fat tissue. Moreover, there are very important interactions among the various cell types that are critical to the proper functioning of the tissue. In view of the huge increase in obesity rates in the United States, and its negative impact on health, new attention has been focused on the development, maintenance, and plasticity of this important tissue.

Analysis of adipose tissue histogenesis and remodeling has relied mainly upon descriptive approaches to define cell phenotypes and deduce their transition to mature cells. In humans, adipose tissue appears as distinct lobules during the second trimester of fetal development. The specific timing of adipose tissue histogenesis and fat cell differentiation varies according to location in the body. Adipocytes within fat tissue are thought to derive initially from mesenchymal progenitors capable of differentiating into bone, muscle, as well as fat. Mesenchymal cells that are highly committed to the adipocyte lineage first appear closely associated with vessel formation, and there appears to be a close reciprocal association of developing fat cells with angiogenesis. This is not surprising since early committed cells express lipoprotein lipase that is targeted at the capillary lumen, and provides the mechanism for the transport of dietary triglyceride to fill the developing fat cells. As fat cells develop, triglycerides coalesce into small lipid droplets (nearly all of which are triglycerides) within the cytoplasm that eventually fuse to form a large single lipid droplet. The typical mature adipocyte is relatively large (30–50 micron diameter) and can reach a size of greater than 120 μm under certain conditions (Fig. 2).

Experimental investigations of adipose tissue have mainly utilized rodent models, although it is important to note that the ontogeny of adipose tissue varies widely among species, and even among fat depots within a given species. In rodent models, white adipose tissue generally appears late in embryonic development and continues to expand and differentiate during the neonatal period prior to weaning. Classic "flash" labeling experiments with an ^{3}H thymidine have shown that most proliferation of cells that are destined to become adipocytes occurs in the first postnatal week. Mitoses are mostly found in poorly differentiated mesenchymal cells that are closely associated with developing capillaries. The transition of cells from mesenchymal progenitors to mature cells can be deduced by evaluating the cellular distribution of ^{3}H label over time following

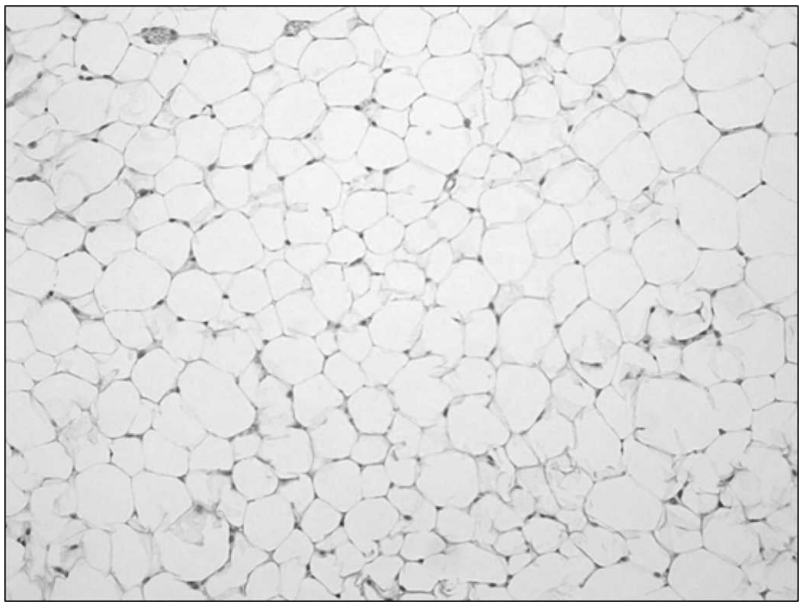

Fig. 2 Histological appearance of normal mouse adipose tissue. Shown is a 6-µm paraffin section stained with hematoxylin and eosin. Note the single large lipid droplet with numerous interstitial cells.

flash labeling. Over time, the percentage of labeled mesenchymal cells declines as the label appears in cells that have accumulated lipid. In contrast, labeling of endothelial cells remains relatively constant. These data suggest a dynamic process in which mature adipocytes are derived from committed mesenchymal progenitors that divide and develop into adipocytes. Interestingly, nearly 90% of the initial label is lost by five months, strongly indicating that cellular renewal occurs throughout life. In this regard, it is well established that cells can be isolated from human and rodent adipose tissue that readily differentiate into mature adipocytes *in vitro*. Indeed, pluripotent progenitors derived from adult adipose tissue may have numerous therapeutic applications. These observations indicate that adipose tissue contains a significant population of committed progenitors that are capable of contributing to tissue renewal and remodeling under appropriate conditions.

Under normal laboratory conditions, cellular proliferation in rat adipose tissue drops to very low levels after weaning. Nonetheless, a variety of physiological and pharmacological conditions reveal dynamic regulation of adipose tissue. For example, Hirsch and colleagues demonstrated in the 1970s that the obesity produced by high fat diets in rats involves both fat cell hyperplasia as well as hypertrophy. Fat cell renewal has also been observed after partial lipectomy, and elevated fat cell turnover has been observed in models of hypothalamic obesity. One of the best examples of physiological adipose tissue plasticity occurs in seasonal fat deposition of hibernators. Although the mechanisms involved in fat cell proliferation are largely unknown, adipose tissue itself is a rich source of growth factors and cytokines

that could trigger tissue expansion. As discussed below, certain pharmacological agents that exhibit antidiabetes properties in rodents and man target receptors that are enriched in fat tissue, and produce pronounced tissue remodeling that is likely related to the therapeutic actions of these agents.

3.2 Differentiation of Adipocytes from Precursor Cells

Together with adipocyte size, the number of adipocytes in the body is an important determinant of obesity and of multiple parameters of energy metabolism. The number of adipocytes present in an organism is determined to a large degree by the adipocyte differentiation process that generates mature adipocytes from fibroblast-like preadipocytes. Many of the molecular details of this process are now known, and the following section summarizes our current understanding of the molecular control of adipogenesis. It is important to note that our understanding of how adipocytes are generated from precursor cells is based primarily on cell culture models of adipogenesis such as the mouse 3T3L1 cell line. While these cell lines are very amenable to experimentation, they produce adipocytes that are strikingly different in some respects than native adipocytes found in adipose tissue *in vivo*. For example, fully differentiated 3T3L1 adipocytes are multilocular (contain multiple lipid droplets), while native adipocytes in white fat (the predominant type of adipose tissue in humans) display a unilocular distribution of lipid (compare Figs. 2 and 3). While we know that many of the characteristics of adipocyte differentiation in cultured cell lines are also important features of *in vivo* adipogenesis, it is important to bear in mind that some aspects of adipogenesis that have been learned from cell culture systems, as described below, may differ from the process as it occurs *in vivo*.

When cultured preadipocyte cultures are grown to confluence and cease cellular division (growth arrest), they can be induced to differentiate into adipocytes by treatment with an adipogenic hormonal cocktail containing insulin, dexamethasone, and an inducer of intracellular cAMP concentration. One of the first steps in the process of adipogenesis is the reentry of growth-arrested preadipocytes into the cell cycle and the completion of several rounds of clonal expansion. Multiple genes involved in the cell cycle control are required for this step to proceed, including the tumor suppressor retinoblastoma protein (Rb) and several cyclin-dependent kinases and their inhibitors (p18, p21, and p27). This and the subsequent steps of the program of adipogenesis are controlled, to a large degree, by a cascade of gene expression events regulated by a small set of transcription factors. Two families of transcription factors have emerged as the key determinants of this process: the three CCAAT/enhancer-binding proteins C/EBP α, β and δ, and the two-peroxisome proliferator-activated receptors gamma-1 and gamma-2 (PPARγ1 and PPARγ2).

One of the initial steps in the transcriptional cascade in response to adipogenic signals is the rapid induction of C/EBP β and δ expression. These transcription factors orchestrate cell cycle reentry by stimulating the expression of the CDK inhibitor p21, which acts to inhibit the Rb protein and relieve its block on cell cycle progression. C/EBP δ and β have also been shown to induce expression of the gene for the PPARγ transcription factor that plays

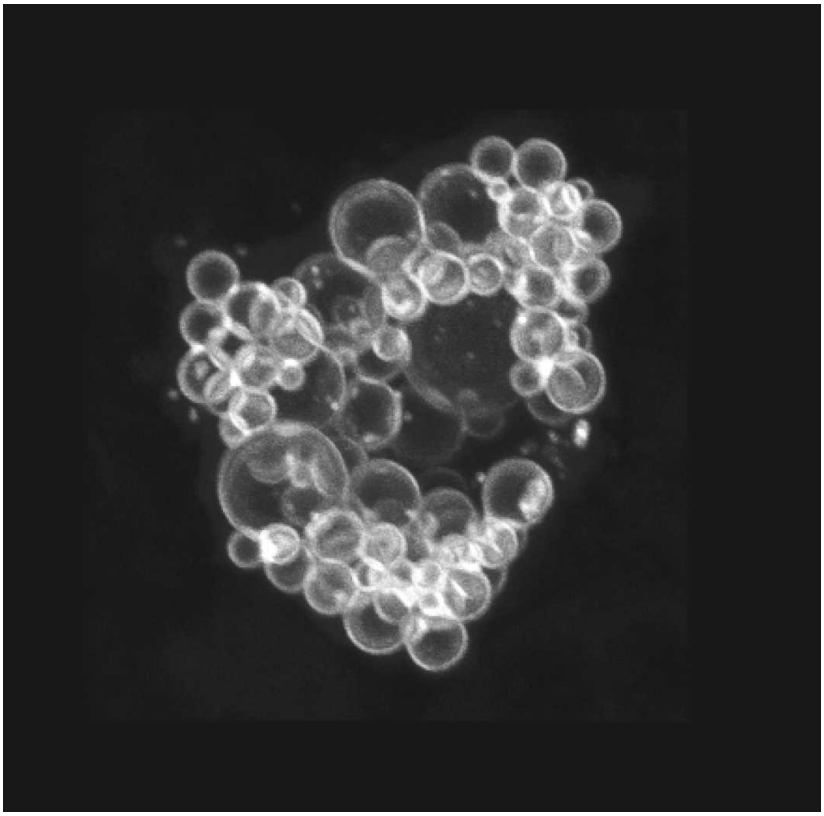

Fig. 3 Fluorescence micrograph of a cultured adipocyte expressing EGFP–perilipin fusion protein. A C3H 10T1/2 mesenchymal cell was differentiated in culture and transfected with an expression vector encoding perilipin fused to enhanced green fluorescent protein. Note the localization of the fluorescence to surface of the numerous lipid droplets (see color plate p. xxi).

a key role in the terminal differentiation of adipocytes (discussed in more detail below). The importance of C/EBP β and δ for adipogenesis was clearly demonstrated by loss-of-function and gain-of-function genetic studies in mice. Overexpression of either C/EBP β or δ in preadipocytes enhanced adipogenesis, while embryonic fibroblast cells derived from mice lacking either C/EBP β or δ had reduced levels of adipogenesis compared with wild type.

The induction of C/EBP β and δ is immediately followed by an increase in PPARγ and C/EBPα expression. PPARγ is a member of the nuclear hormone receptor family of ligand-activated transcription factors. It is absolutely required for adipocyte differentiation, as a genetic knockout of the PPARγ gene in mice prevents the development of all fat tissue. In addition to its crucial role in adipocyte differentiation PPARγ is the receptor for the thiazolidinedione (TZD) class of antidiabetic drugs, indicating that it is also important in metabolic regulation in adult organisms. In mice and humans there are two isoforms, PPARγ1 and PPARγ2, which are derived from the same gene by

alternative promoter usage and RNA splicing. While the expression of PPARγ2 is restricted almost exclusively to adipocytes, PPARγ1 has a broader pattern of expression although it is still most abundant in adipocytes. Although PPARγ2 is identical to PPARγ1 except that it contains an additional 28 amino acids on its N-terminus, it appears that the two proteins have distinct activities with regard to adipocyte differentiation. When the expression of the PPARγ2 isoform was blocked, adipogenesis was more strongly inhibited than when the PPARγ1 isoform was blocked. In addition, exogenous delivery of PPARγ2 into PPARγ deficient cells was able to completely restore the adipogenesis, whereas overexpression of PPARγ1 had little effect. It may be that PPARγ1, which is already expressed in preadipocytes, behaves as a priming factor (along with C/EBP β and δ) for the induction of PPARγ2 or for the generation of endogenous PPARγ ligands that play a role in later stages of adipogenesis.

As the program of differentiation proceeds, the expression of C/EBPα rises immediately after the increase in PPARγ2 expression. Like PPARγ, C/EBPα also plays an essential role in adipose development as targeted gene knockout in mice results in embryonic lethality and failure to develop normal adipose tissue. There has been an intense research effort to understand the relationship between these two transcription factors and the role they play in adipogenesis. Several studies have demonstrated that PPARγ2 and C/EBPα coregulate each other's expression. Mice with reduced PPARγ expression due to heterozygous gene knockout displayed a drastically reduced level of C/EBPα, and mice with disrupted C/EBPα expression showed a reduced level of PPARγ. Introduction of either PPARγ or C/EBPα into NIH3T3 cells is sufficient to convert these normally nonadipogenic cells from fibroblasts into adipocytes. However, it is unclear if either of the transcription factors, completely on its own, could induce adipogenesis. Taken together, most of the recent evidence supports the model that while both of the transcription factors work coordinately to carry out adipogenesis, PPARγ2 probably plays the primary role, while C/EBPα may act mostly by inducing and maintaining PPARγ2 expression. C/EBPα may also function to regulate the transcription of genes involved in the metabolic actions of insulin such as glucose transporter 4 (Glut 4). Clearly, PPARγ and C/EBPα are key transcription factors in adipogenesis, acting synergistically to generate fully differentiated, insulin-responsive adipocytes.

Although our understanding of adipocyte differentiation, as described above, is derived from work in cultured cell lines, it is likely that many of the pathways and key components also play an important role in generating adipocytes from precursor cells *in vivo* and in the remodeling of adipose tissue as it occurs during certain metabolic stress (see Sect. 3, above) or treatment with specific pharmacological agents (see Sect. 5, below).

4 Adipose Dysfunction and Metabolic Disease

Just as our appreciation of how active a role the adipose tissue plays in the metabolic regulation has grown in recent years, so too has the interest in the role that adipocytes play in the development (and treatment) of metabolic diseases such as obesity and diabetes. The investigation of the role of adipose tissue in these diseases has taken on added significance in recent years

because of the dramatic rise in the prevalence of these related disorders. Although the causal relationship between diabetes and obesity is not fully understood, a likely common link is the adipocyte. Given that adipose tissue serves to buffer excess lipid, and to confer insulin resistance that is associated with inappropriate accumulation of lipid in nonadipose cells, it is not surprising that the dysfunction in adipose tissue could profoundly affect diabetes susceptibility. The inability of adipose tissue to buffer circulating lipid levels and concurrent accumulation of lipid in muscle and liver may, in fact, be an early event in the development of diabetes. This potential link between adipose tissue function and diabetes raises the new and exciting possibilities for the development of therapeutic agents to treat diabetes. Drugs targeted to very specific metabolic or hormonal functions in the adipocyte could potentially have a profound beneficial effects on metabolism throughout the body. The following is a summary of the known defects in adipose function and their effects on energy metabolism and glucose homeostasis. We will also review what is known about the antidiabetic thiazolidinedione drugs that are thought to have their effects by modifying adipocyte physiology.

4.1 Obesity – Too Much Fat

A long-standing observation in the field of diabetes research is that obese individuals have an increased risk of developing insulin resistance and type 2 diabetes. The current epidemic of diabetes in western cultures began about thirty years ago and correlates precisely with the concurrent explosion of obesity. This has led to the assumption that there is a functional, or causative relationship between these two disorders; that the presence of obesity increases susceptibility to diabetes. Although the relation between these two metabolic disorders is unmistakable, it is not understood how obesity precipitates the multiple functional defects that precede overt diabetes. However, an emerging candidate is the acquired inability of adipocyte to protect important tissues and cells throughout the body from exposure to excessive lipids.

Normally, excess calories are stored in the body in the form of triglycerides, mainly in adipocytes of white fat tissue. However, nonadipocyte cells also store low levels of triglycerides to meet internal metabolic requirements. In these cells, the amount of stored triglyceride is maintained within a very narrow range. A fatty acid homeostatic system functions in healthy individuals to direct excess fat to adipocytes while maintaining normal amounts of triglyceride in nonadipocytes. Under conditions of chronic positive energy balance and ensuing obesity, however, the capacity for adipose tissue to buffer excess lipid energy may be exceeded, resulting in the pathological accumulation of lipid within key metabolic tissues.

The elevation of free fatty acid (FFA) in the blood is predictive of conversion from impaired glucose tolerance to diabetes, suggesting that FFA themselves could contribute to organ defects that precede type 2 diabetes, such as insulin resistance of skeletal muscle, and reduced pancreatic insulin secretion. More recently, it has been shown that intracellular accumulation of lipid within myocytes strongly predicts insulin resistance *independent of the magnitude of obesity*. Thus, it is not the accumulation of lipid in fat cells *per se* that is problematic, rather it is the redirection of lipid to other key cells that occurs once the capacity of the adipocyte to handle

lipid has been exceeded. This condition is perhaps most dramatically illustrated by patients with lipodystrophy, who are severely insulin-resistant and develop diabetes at an early age. These individuals lack certain adipose tissue depots and therefore have reduced capacity to buffer excess lipid (presented in more detail below). Viewed from this perspective, obesity leads to diabetes when abnormal amounts of triglyceride accumulate in nonadipose tissues such as skeletal muscle and pancreatic islets. Excess triglyceride deposition in nonadipocytes might generate a lipid environment that interferes with cellular physiology and gene expression in ways that contribute to insulin resistance and β-cell failure associated with type 2 diabetes.

4.2 Lipodystrophy – Too Little Fat

The model described above proposes that obesity promotes the development of type 2 diabetes because adipocytes from obese individuals have reduced capacity for further lipid storage, which leads to inappropriate fat accumulation in nonadipose tissue. As mentioned above, the effects of aberrant amounts of adipose tissue on physiology are best illustrated in the rare, but informative, lipodystrophy syndromes. These inherited and acquired syndromes are characterized by the partial or complete loss of adipose tissue, insulin resistance, and diabetes. Several mutations that cause inherited forms of lipodystrophy, such as partial familial lipodystrophy (PFLD), have been identified. One of the most common genetic defects in PFLD are mutations in the gene encoding the nuclear lamin a/c protein. Although the mechanism by which mutant lamin a/c protein causes lipodystrophy is not known at this time, it seems likely that the protein, which plays a fundamental role in the function of the nucleus, is required for normal adipocyte differentiation of maintenance. Patients carrying PFLD mutations exhibit an absence of adipose tissue in their extremities, elevated circulating lipids, abnormally high levels of intracellular triglyceride in muscle and liver, and diabetes. Interestingly, mutations causing PFLD have recently been identified in the PPARγ gene, underscoring the key role of this transcription factor in the development and maintenance of adipose tissue.

The conclusions derived from observations of human lipodystrophy syndromes are strongly supported by animal models of lipodystrophy. Several different genetic methodologies have been used to generate mice that have reduced amounts of adipose tissue. Like their human counterparts, these animals invariably exhibit elevated circulating lipids, abnormally high levels of intracellular triglyceride levels in multiple tissues including muscle and liver, severe insulin resistance, and diabetes. Interestingly, these metabolic defects can be improved by transplanting adipose tissue back into the fatless mice. These findings clearly illustrate the vital role that adipose tissue plays in protecting the organism from abnormal lipid accumulation and its deleterious effects on metabolism.

5 The Adipocyte as a Therapeutic Target for Metabolic Disease

As our understanding of the importance of adipose tissue in controlling metabolism has grown, so too has the realization that therapeutic agents designed to modify adipocyte physiology could provide new avenues for the treatment of diabetes, obesity, and other metabolic

diseases. As described above, our current understanding of the role of adipose in protecting other tissue from deleterious lipid accumulation suggests that drugs acting on this aspect of adipocyte function might have beneficial effects. Likewise, the observations (also described above) on adipocyte derived hormones and their metabolic activities, suggests that therapeutic agents modulating the production of key adipokines could also improve certain metabolic parameters. The view that drugs acting on adipocytes could be useful is reinforced by the relatively recent observation that a major class of antidiabetic drugs, the thiazolidinediones, have direct effects on adipocytes. Although this is an active area of research, a generally accepted model of TZD action has emerged in which the antidiabetic effect of these drugs is mediated by activation of the PPARγ transcription factor in adipocytes. The following is a review of our current understanding of how activation of PPARγ in adipocytes might improve insulin sensitivity and other metabolic parameters. This model can serve as a general example of how modification of adipocyte physiology could improve whole body metabolic status.

5.1 Antidiabetic PPARγ Ligands Act on Adipocytes

In patients with type 2 diabetes, treatment with TZD compounds results in a dramatic improvement in peripheral insulin sensitivity and a reduction in plasma glucose concentrations. The TZD compounds were first identified in the 1980s as antidiabetic agents in rodents, well before the discovery of the PPARγ receptor and in the absence of any knowledge of their mechanism of action. In the 1990s, it was discovered that TZDs could activate PPARγ and cause the differentiation of preadipocytes into adipocytes and it is now generally accepted that the antidiabetic activities of the TZDs are mediated by activation of PPARγ. Perhaps the clearest evidence that PPARγ activation mediates the antidiabetic effects of these drugs are the recently discovered synthetic ligands for PPARγ that have been selected exclusively for their ability to activate the receptor. These non-TZD PPARγ agonists show very similar antidiabetic activity to the TZDs.

Although the exact mechanism by which these drugs improve peripheral insulin sensitivity and reduce plasma glucose concentration is not fully understood, several general possibilities have emerged. First, TZDs may have a beneficial effect on metabolism by increasing the fat cell number and size, leading to greater lipid storage capacity and increased protection of nonadipose tissues from the deleterious effects of excess lipid accumulation. Another scenario is that, PPARγ agonists act on the mature adipocyte to alter the production of adipose-derived hormones or metabolic signals that function to improve metabolic parameters in other tissues and organs such as muscle, liver and pancreas. Finally, it is also possible that TZDs exert some of their metabolic effects through PPARγ present in nonadipose tissues such as skeletal muscle.

One feature of TZD treatment that could be central to the therapeutic actions of these compounds is a remodeling of adipose tissue. TZD treatment induces the appearance of clusters of small multilocular adipocytes and loss of large unilocular adipocytes in Zucker diabetic rats. This effect is also observed in mice treated with TZD compounds as seen in Fig. 4. It has been hypothesized that the newly

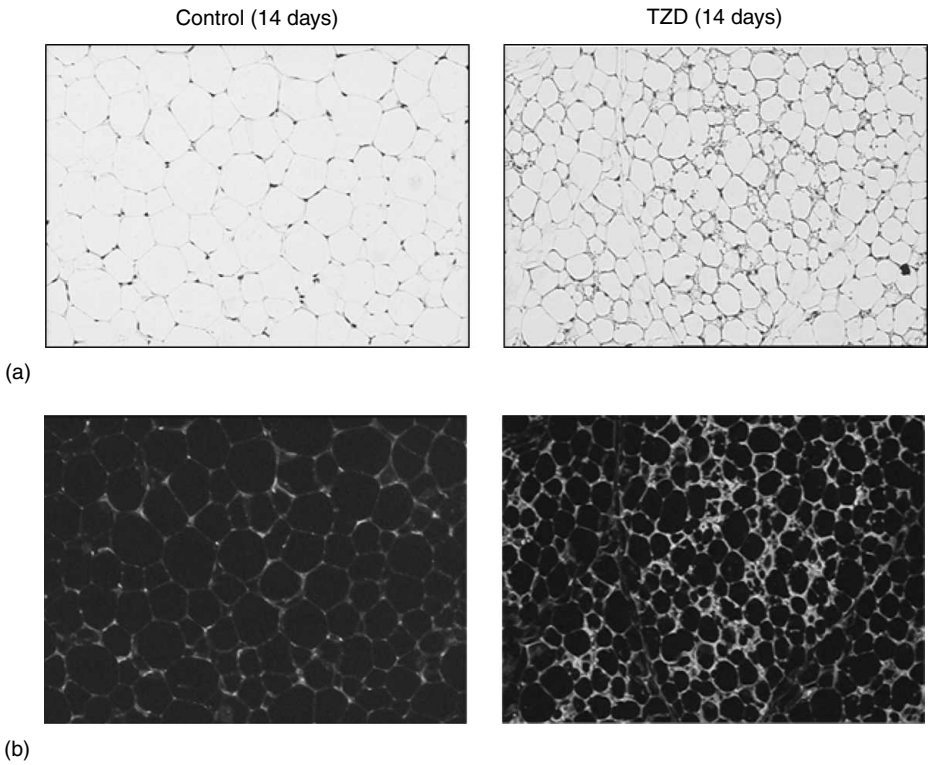

Fig. 4 Thiazolidinedione treatment remodels white adipose tissue. Mice were treated for 2 weeks with the TZD T174, and subcutaneous white fat was processed by (a) hematoxylin and eosin staining and (b) tissue autofluorescence. Note the appearance of numerous clusters of small multilocular adipocytes in TZD-treated tissue.

appearing small adipocytes might be more insulin sensitive and/or secrete lower levels of prodiabetes hormones and thereby contribute to the insulin-sensitizing effects of the drug. It is also possible that the increased number of smaller adipocytes, especially in the appropriate adipose beds, may improve the ability of adipose tissue to store excess lipid and reduce deleterious accumulation of triglyceride in muscle, liver, and pancreatic islets. In support of this possibility is the observation that many of the known target genes for PPARγ, whose expression would presumably be activated upon TZD treatment, are involved in lipogenesis. The increased rates of lipogenesis resulting from gene activation may increase the capacity of adipocytes to store lipid, thereby preventing triglyceride accumulation (and lipotoxicity) in nonadipose tissue. Whether the small adipocytes are derived from stem cell mitosis, recruitment of committed preadipocytes, or possibly by division of mature cells is not known. The loss of large fat cells was attributed to cellular apoptosis; however, the impact of TZD treatment on the fate and turnover of mature adipocytes has not been investigated directly.

Consistent with the observations of adipose tissue remodeling is the increased subcutaneous fat mass, and reduced

visceral fat mass seen in diabetic patients treated long-term with TZDs. Visceral fat is known to be more lipolytic in response to catecholamine stimulation than subcutaneous fat, and to efficiently deliver free fatty acids and other secreted factors to insulin-sensitive tissues such as liver and muscle, possibly causing an increase in insulin resistance. Although intrinsic metabolic differences between subcutaneous and visceral fat are not completely understood, current evidence suggests that subjects with increased visceral fat are at considerably higher risk for diabetes and cardiovascular complications than those with increased subcutaneous fat. These observations, plus the demonstration that PPARγ levels are higher in subcutaneous than in visceral fat, raise the possibility that PPARγ activation by TZDs is fat depot specific, and that differential activation of PPARγ in subcutaneous fat leads to a beneficial reproportioning of key metabolically active adipose beds.

The other possible mechanism by which activation of PPARγ in adipocytes could have effects on metabolism throughout the body, is by modulation of adipokine production. Adiponectin is an excellent candidate for a fat-derived hormone mediating the antidiabetic effects of PPARγ ligands. As described above, adiponectin has antidiabetic and antiobesity activity when introduced into rodents. Importantly, it has recently been demonstrated that levels of adiponectin are increased in patients treated with TZDs and that its expression in adipocytes is induced by PPARγ agonists. Another possibility is that the adipokine, resistin is negatively regulated by PPARγ. It has been reported that in some models, treatment with TZDs results in a reduction of resistin synthesis, which would have beneficial effects on insulin sensitivity. Finally, TZDs, could suppress expression of genes, such as TNFα and PAI-1, that might also contribute to systemic insulin resistance. Interestingly a mutual antagonism exists between TNFα and PPARγ; TNFα inhibits PPARγ expression in adipocytes whereas PPARγ activation by TZDs can partially overcome the diabetogenic effects of TNFα, potentially explaining at least some of the insulin-sensitizing activity of PPARγ ligands.

While there is still obviously a great deal to learn about which of these many possible mechanisms actually mediate the effects of PPARγ activation in adipose tissue, it is clear that an understanding of how these drugs affect adipose physiology will provide many clues into the complex pathways by which the adipocyte influences metabolism throughout the organism.

Keywords

Aggregates
The association of nonnative protein molecules through intermolecular hydrophobic interactions.

Amyloid Fibrils
Ordered aggregates.

Inclusion Bodies
Insoluble, amorphous, disordered aggregates.

Molecular Chaperones
Proteins that assist protein folding within cells.

Protein Folding
The process by which polypeptide chains acquire their three-dimensional and functional structure.

Three dimensional–Domain Swapping
An aggregation mechanism in which one domain in a multidomain protein is swapped with the same domain of another molecule.

Protein misfolding and aggregation are frequent phenomena that occur under different conditions *in vivo* as well as *in vitro*. Aggregation is a serious problem affecting both the production of proteins in the biotechnology and pharmaceutical industries and human health. The aggregates are formed from nonnative proteins through intermolecular interactions that compete with intramolecular interactions. There is thus a kinetic competition between proper folding and misfolding, which can generate aggregates.

Recent evidence for transient association of intermediates during *in vitro* refolding has been obtained for several monomeric proteins. Irreversible and insoluble aggregates are formed in an off-pathway folding process; their formation is concentration dependent and could be prevented by using very small protein concentrations. These aggregates can dissociate and dissolve only in the presence of high concentrations of denaturant. The mechanisms involved in these aggregation processes will be discussed in light of the so-called *new view* of protein folding.

The environmental conditions within cells are markedly different from those used in *in vitro* refolding studies. In the production of recombinant proteins in foreign hosts, the formation of disordered aggregates, that is, inclusion bodies, is often observed. However, aggregation can also result in the formation of amyloid fibrils, which are ordered aggregates. These amyloid formations are at the origin of serious diseases.

1 Introduction

Protein misfolding and aggregation have been recognized for many years as common processes. Aggregation can occur under various conditions. The aggregation of which we are speaking is very different from the precipitation of a native protein at the isoelectric point or upon salting out, which can be reversed under appropriate conditions. In the precipitate, the protein remains in a native conformation. The aggregates, however, are formed from partially folded intermediates and result from intermolecular interactions, which compete with intramolecular interactions. Thermal denaturation of proteins is frequently accompanied by the formation of aggregates leading to the irreversibility of the process. As early as 1931, Wu, in a review on protein denaturation, distinguished between aggregation and precipitation. The aggregated species are not in equilibrium with the soluble species, complicating experimental approaches.

Aggregation has been reported to occur during the *in vitro* refolding of monomeric as well as oligomeric proteins, lowering the refolding yield. As mentioned above, the use of very low protein concentrations could prevent protein aggregation. However, during the folding of nascent polypeptide chains biosynthesized within prokaryotic and eukaryotic cells, aggregates can accumulate. The overexpression of genes in foreign hosts often result in aggregated nonnative proteins called *inclusion bodies*, which are disordered aggregates, leading to serious limitation in the production of recombinant proteins. It is a real problem needing a lot of effort to fully exploit the sequence information contained in the genome projects. Ordered aggregates resulting in amyloid fibrils lead to a number of serious human diseases such as Alzheimer's disease and the transmissible spongiform encephalopathies. The formation of amyloid aggregates has also been reported in *in vitro* experiments.

Experimental and theoretical studies together have provided significant insights into the mechanisms of protein folding, also allowing a better understanding of the aggregation processes.

The following different aspects of protein aggregation must be considered:

1. Theoretical and methodological aspects of protein folding, misfolding, and aggregation including the detection of aggregates and the mechanisms of aggregation processes.
2. Protein aggregation in the cellular environment including the folding into the cell, the role of molecular chaperones, and the formation of different aggregate morphologies, as well as the pathological consequences.

2 Protein Folding, Misfolding, and Aggregation

2.1 The New View of Protein Folding

The question of the mechanisms of protein folding has intrigued scientists for many decades. As early as the 1930s, attempts to refold denatured proteins were published, but significant progress began to be made when Anfinsen successfully refolded, denatured, and reduced ribonuclease into the fully active enzyme. In 1973, he stated the fundamental principle of protein folding referred to as the Anfinsen postulate: ''all the information necessary

to achieve the native conformation of a protein in a given environment is contained in its amino acid sequence.'' The thermodynamic control of protein folding was considered to be a corollary of the Anfinsen postulate, meaning that the native structure is at a minimum of the Gibbs free energy. This statement was discussed by Levinthal in a consideration of the short time required for the folding process *in vitro* as well as *in vivo*. It was concluded that a random search of the native conformation among all possible ones would require an astronomic time and is therefore unrealistic. Thus, it is clear that evolution has found an effective solution to this combinatorial problem. This is referred to as the Levinthal paradox and has dominated discussions for the last three decades.

In order to understand how the polypeptide chain could overcome the Levinthal paradox, different folding models were proposed and submitted to experimental tests. Kinetic studies were carried out to follow the folding pathway. A considerable number of experiments were performed to detect and characterize the folding intermediates. A stepwise sequential and hierarchical folding process in which several stretches of structure are formed and assembled at different levels following a unique route was supported by a majority of scientists for many years. According to this view, misfolded species could be formed from folding intermediates leading to the formation of aggregates in a kinetic competition with the correct folding.

Progressively, with the development of computers, theoretical studies have approached the folding problem, using simplified models to take into account the computational limitations in simulations of the folding from the random coil to the native structure. Different methods were developed using either lattice models or molecular dynamics simulations. In the lattice model, the polypeptide chain is represented as a string of beads on a two-dimensional square lattice or on a three-dimensional cubic lattice. The interactions between residues (the beads) provide the energy function for Monte Carlo simulations. In such simplified models, the essential features of proteins, that is, the heterogeneous character (hydrophobic or polar) of the interactions and the existence of long-range interactions, were included to explore the general characteristics of the possible folds. Lattice models were first applied to protein folding by Go and coworkers while simple exact models were initiated by Dill and his group, and have been used by several theoreticians. From the lattice simulations, insights into possible folding scenarios have been obtained, providing a basis for exploring the general characteristics of folding for real proteins. The exploration of such models supplies useful information that can be submitted to experimental tests.

The so-called ''new view'' has evolved during the past 10 years from both experiment and theory with the use of simplified models. It is illustrated by the metaphor of the folding funnel introduced in 1995 by Wolynes and coworkers. The model is represented in terms of an energy landscape and describes the thermodynamic and kinetic behavior of the transformation of an ensemble of unfolded molecules to a predominantly native state as illustrated in Fig. 1. According to this model, there are several micropathways, each individual polypeptide chain following its own route. Toward the bottom of the funnel, the number of protein conformations decreases as does the protein entropy. The steeper the slope, the faster the folding. As written by Wolynes et al., ''To fold, a protein navigates with remarkable ease

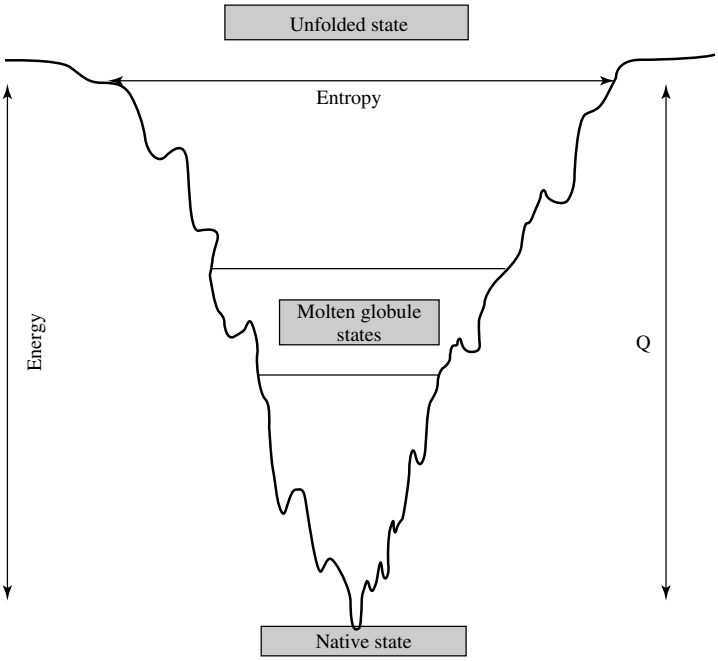

Fig. 1 Schematic representation of the folding funnel. Q is the number of native interactions.

through a complicated energy landscape.'' Thus, a wide variety of folding behaviors emerge from the energy landscape, depending on the energetic parameters and conditions. The folding rate could be slowed by ripples in the energy landscape corresponding to local minima populated by transiently stable intermediates. In a rugged energy landscape with kinetic traps formed by energy barriers, the folding will be even slower. When local energy barriers are high enough, protein molecules could be trapped and possibly aggregate.

The new view has progressively replaced the classical one of a unique sequential pathway and is now quite generally accepted. It is similar to the jigsaw puzzle model proposed in 1986 by Harrison and Durbin, suggesting the possibility of multiple folding routes to reach a unique solution. Many experimental results are consistent with this view. There is an increasing amount of evidence showing that the extended polypeptide chain folds through a heterogeneous population of partially folded intermediates in fluctuating equilibrium. Several alternative folding pathways have been observed for different proteins. From the convergence of theoretical and experimental studies, a unified view of the folding process has progressively emerged, also providing an explanation for the aggregation processes.

2.2 Detection of Aggregates during the Refolding Process

2.2.1 Transient Aggregation

Several observations indicate that transient aggregation could occur during *in vitro* protein refolding. Direct evidence for the

transient association of intermediates has been obtained from small angle X-ray scattering, in the case of apomyoglobin by Doniach and his group, and in the case of carbonic anhydrase by Semisotnov and Kuwajima, and by Silow et al. During the refolding of phosphoglycerate kinase, rapidly transient multimeric species (dimers, trimers, and tetramers) yielding to the native monomeric protein have been detected by Pecorari et al. These species are not in equilibrium, but are formed rapidly and disappear in the slow folding step. Unlike classical aggregates, their distribution does not depend on protein concentration, and they are produced at concentrations as low as 0.05 μM. The distribution of the oligomers is completely established at the end of the fast refolding step. To take into account all these observations, a model, which is formally similar to a reaction of copolymerization between two types of monomers, has been proposed. In this model, the refolding of the protein produces two types of intermediate conformers that can associate with the same or the other type. In the latter case, the association cannot be extended further (Fig. 2). Transient multimeric species have also been observed during the refolding of the isolated N-terminal domain under conditions in which neither the whole native protein nor the folded isolated N-domain associate. However, they cannot transform to the native form in the absence of the interactions with the complementary

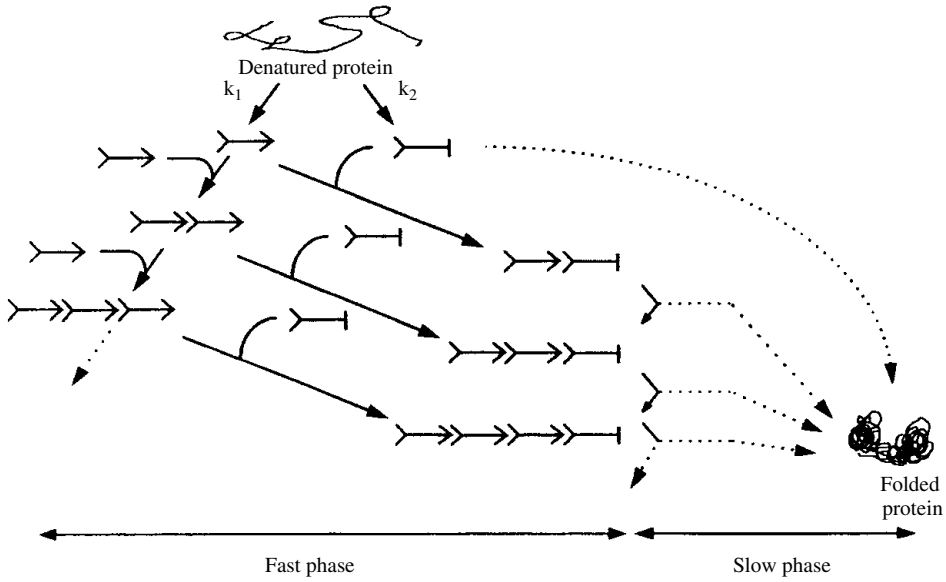

Fig. 2 Model proposed for the formation of transient multimeric species during the refolding of yeast phosphoglycerate kinase. Two types of conformers are produced in the early step of folding. One of these can be directionally extended by association with either the same conformer or another type of conformer. In this last case, the association cannot be further extended. The distribution of species results from a kinetic competition between two kinetic processes. (Reproduced from Pecorari, F., Minard, P., Desmadril, M.,Yon, J.M. (1996) Occurrence of transient multimeric species during the refolding of a monomeric protein, *J. Biol. Chem.* **271**, 5270–5276.)

domain indicating the importance of long-range interactions in directing the correct folding. Such species have not been observed with the C-terminal fragment. Thus, the occurrence of transient multimeric species arising from partially folded intermediates through hydrophobic interactions does not prevent the correct folding of a monomeric protein.

2.2.2 **Irreversible Aggregation**

Thermal unfolding of proteins is frequently accompanied by the formation of aggregates and therefore behaves as an irreversible process. It occurs at temperatures that vary widely according to the protein, since the temperature of optimum stability depends on the balance between hydrogen bonds and hydrophobic interactions. Generally, the products of thermal denaturation are not completely unfolded and retain some structured regions. At the end of the thermal transition, the addition of a denaturant such as urea or GdnHCl frequently induces further unfolding.

An apparent irreversibility at a critical concentration of denaturant has been observed during the refolding of monomeric as well as oligomeric proteins. It was reported for the first time by M.Goldberg and coworkers for the refolding of β-galactosidase, and for tryptophanase. It was also observed for a two-domain protein, horse muscle phosphoglycerate kinase by Yon and coworkers. In the latter study, when the enzyme activity was used as a conformational probe of the native structure, an irreversibility was observed for a critical concentration of denaturant equal to 0.7 M $\pm$ 0.1 M GdnHCl, a concentration very close to the end of the transition curve. Such irreversibility was found to be concentration dependent. For protein concentrations higher than 30 μM, restoration of enzyme activity was practically null. The formation of irreversible nonnative species was found to be temperature dependent; it was practically abolished at 4 °C, suggesting that aggregation occurs through hydrophobic interactions. The aggregation also depends on the time of exposure of the protein to the denaturant. When the unfolding–refolding process was observed using structural signals such as fluorescence or circular dichroism, it appeared completely reversible whatever the final denaturant concentration.

Another example is provided by rhodanese, a two-domain monomeric protein. During refolding at low denaturant concentration, an intermediate accumulates with partially structured domains and apolar surfaces exposed to the solvent, leading to the formation of aggregates. The aggregation can be prevented by refolding the protein in the presence of lauryl maltoside.

Most of the examples discussed above are related to multidomain proteins. Another degree of complexity appears in the folding of oligomeric proteins. It is generally accepted that the early steps of the process are practically identical to the folding of monomeric proteins. In the last step, subunit association and subsequent conformational readjustments yield the native and functional oligomeric protein. The correct recognition of subunit interfaces is required to achieve the process. The overall process of the folding of oligomeric proteins was extensively studied by Jaenicke and his coworkers for several enzymes and described in reviews. As with monomeric proteins, the formation of aggregates is concentration dependent. The kinetics of aggregation are complex and multiphasic, indicating that several rate-limiting reactions are involved in the process. In an attempt to characterize these aggregates, it was shown that noncovalent interactions occur between monomeric species with

partially restored secondary structures. The aggregates formed by either heat or pH denaturation can be disrupted in 6 M GdnHCl into monomeric unfolded species and then renatured under optimal conditions to yield an active enzyme. Only strong denaturants such as high concentrations of guanidine hydrochloride are efficient in this disruption process.

The presence of covalent cross-links such as disulfide bridges in a protein molecule can complicate the refolding of the denatured and reduced protein resulting in the formation of incorrect and intramolecular disulfide bridges leading to further aggregation. The first well-documented studies were performed by Anfinsen and his group on the refolding of reduced ribonuclease. The authors showed that the reoxidation of the enzyme produces a great number of species with incorrectly paired disulfide bonds. This scrambled ribonuclease is capable of regaining its native structure in a slow step, a process that is accelerated by the addition of a small quantity of reducing reagent such as β-mercaptoethanol yielding about 100% of active enzyme. The reshuffling of a protein's disulfide bonds takes place through a series of redox equilibria according to either an intramolecular or an intermolecular exchange. To prevent a wrong pairing of half-cystine and further aggregation, the addition of small amounts of reducing reagents or redox mixture is frequently used as investigated by Wetlaufer.

The detection and characterization of aggregates represent an important aspect of folding studies. The aggregation phenomenon can occur without precipitation. Indeed, the degree of association of protein intermediates during folding might be small, depending on the intermolecular interactions, and does not necessarily lead to a visible insolubility. The association state may be determined in several ways. The most common methods, available in any biochemistry laboratory, are gel permeation and sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), used both with and without cross-linking. The detection of aggregates can also be monitored by other hydrodynamic methods such as analytical ultracentrifugation or classical light scattering. The latter method also gives information on the size of the aggregates. Quasi-elastic light scattering is a dynamic technique that can be used to determine macromolecule diffusion coefficients as a function of time, that is, to follow the kinetics of aggregation. Neutron scattering can also be used to detect protein aggregates, and mass spectrometry has become a useful tool as well.

2.3 Mechanisms of Protein Aggregation

A substantial body of information supports the idea that protein aggregation arises from partially folded intermediates through hydrophobic interactions. The formation of aggregates has often been considered as a trivial phenomenon, a nonspecific association of partially folded polypeptide chains to form a disordered precipitate. However, several analyses indicate that aggregation occurs by specific intramolecular associations involving the recognition of a sequence partner in another molecule rather than in the same molecule during the folding process. Analyses of the aggregation mechanisms of various proteins, such as bovine growth hormone and phosphoglycerate kinase, has permitted the identification of specific sites that are critical in the association.

An elegant demonstration of the specificity of aggregation was provided by King

and coworkers. The authors showed that during the *in vitro* refolding of a mixture of two proteins, tailspike endorhamnidase and coat protein from phage P22, no heterogeneous aggregates were formed. Tailspike endorhamnidase is a thermostable trimer whose folding intermediates are thermolabile and either undergo productive folding or form multimeric aggregates (Fig. 3). The P22 coat protein, which comprises the capsid shell of phage P22, yields either a correct fold or "off-pathway" aggregates upon refolding. Both proteins were intensively studied by King and coworkers who first denatured the two proteins in urea and then chose refolding conditions such that aggregation competes with correct folding. Folding and soluble aggregates of the two proteins were characterized either separately or mixed together. No heterogeneous aggregates were found, clearly indicating that only self-association of transient refolding molecules occurs in the formation of soluble multimers.

One mechanism that accounts for the formation of aggregates during refolding of multidomain proteins is domain swapping. This was first suggested by Monod and later proposed by Goldberg and colleagues to account for the formation of aggregates during the refolding of tryptophanase. The concept was foreshadowed by the results of Crestfield and coworkers in 1962. From their experiments based on chemical modification of bovine pancreatic ribonuclease, the authors proposed that the dimer is formed by exchanging the N-terminal fragments. The term *3D domain swapping* was introduced in 1994 by Bennett and coworkers to describe the structure of a diphtheria toxin dimer. The mechanism involves the replacement of one domain of a monomeric protein by the same domain of an identical neighboring

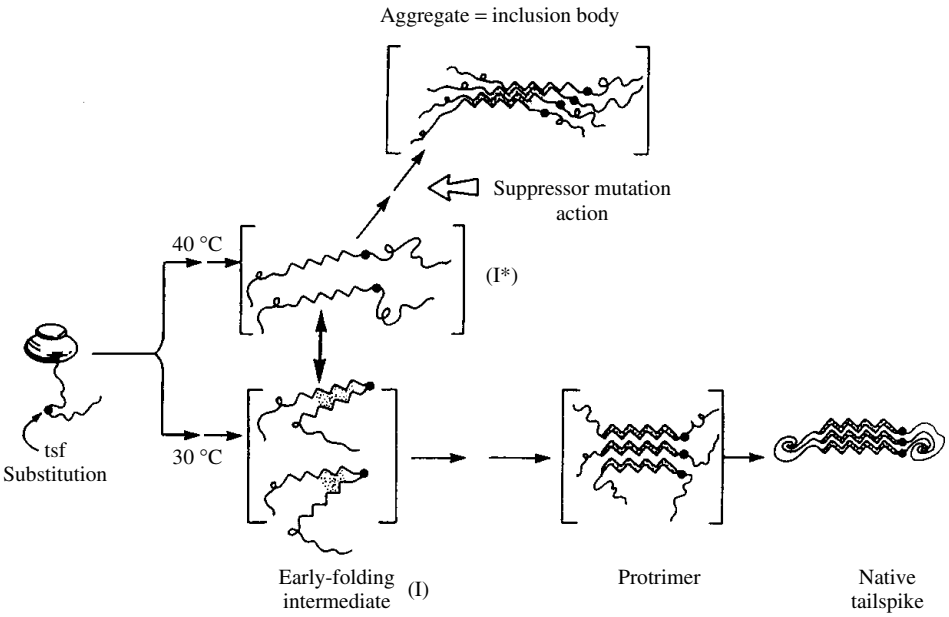

Fig. 3 The folding pathway of the P22 tailspike protein. (From Mitraki, A., King, J. (1992) *FEBS Lett.* **307**, 20–25; reproduced with permission.)

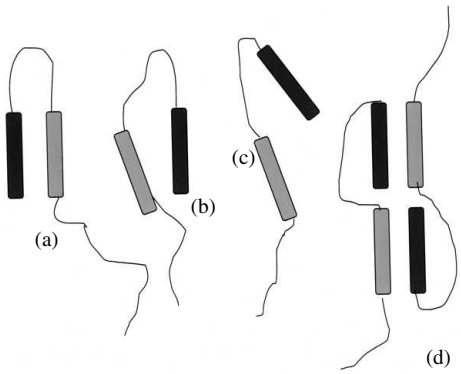

Fig. 4 Schematic representation of domain swapping. (a) monomeric protein, (b) and (c) partially unfolded monomers, (d) domain-swapped dimer.

molecule, thus resulting in an intertwined dimer or oligomer, as defined by Eisenberg and colleagues (Fig. 4). When the exchange is reciprocated, domain-swapped dimers are formed. However, if the exchange is not reciprocated but propagated along multiple polypeptide chains, higher order assemblies or aggregates may form. Domain-swapped oligomers are divided into two types, open and closed. The open oligomers are linear and have one closed interface (closed in the monomer) exposed to the solvent, whereas closed oligomers are cyclic and do not expose a closed interface. Eisenberg and coworkers have defined the structure of the monomer as the ''closed monomer'' and the conformation of the polypeptide chain in the domain-swapped oligomer as the ''open monomer.''

The ability of monomeric proteins to swap structural elements requires the presence of a hinge or linker region that permits the protein to attain the native fold with parts of two polypeptide chains. In fact, domain-swapped structures reveal regions of protein structure that are flexible. Bergdoll and coworkers have suggested that a proline in the linker region, by rigidifying the hinge region in intermediate states, might facilitate domain swapping. Baker and colleagues proposed that strain in a hairpin loop might predispose a protein to domain swapping. The possible role of 3D domain swapping in the evolution of oligomeric proteins has been discussed in several reviews. In the past years, the number of known domain-swapped proteins has increased and today about 40 such structures are solved. One common feature of these proteins is that all the swapped domains are from either the N-terminus or the C-terminus of the polypeptide chain. In this regard, an interesting example arises from the work of Eisenberg and his group on the dimerization of ribonuclease A. This protein forms two types of dimers upon concentration in mild acid. The minor dimer is formed by swapping of its N-terminal α-helix with that of an identical molecule. The major dimer results from the swapping of its C-terminal β-strand. RNase A was also reported to form trimers. On the basis of the structure of the N- and C-terminal swapped dimers, a model was proposed (Fig. 5). This indicates that two types of swapping can occur simultaneously in the same oligomer. Further biochemical studies have supported this model. A less abundant trimer in which only the C-terminal β-strand is swapped and exhibits a cyclic structure was also found. RNase represents the

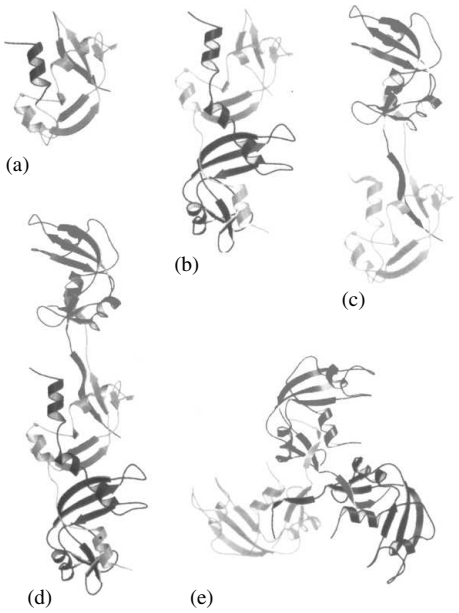

Fig. 5 Domain swapping in ribonuclease. Ribbon diagram of the structures of (a) the ribonuclease A monomer (2.0 Å), (b) the N-terminal swapped dimer (2.1 Å), (c) the C-terminal swapped dimer (1.75 Å), (d) the N- and C-terminal trimer model, and (e) the cyclic C-terminal swapped trimer (2.2 Å) (reproduced from Liu et al. Prot. Sci. **11**, 371, 2002 with permission).

first protein found to form both linear and cyclic domain-swapped oligomers. This protein also was described to form tetramers. Models based on the structures of dimers and trimers were proposed for these tetramers. Two linear models exhibit both types of swapping that occur in one molecule, and a cyclic tetramer shows the swapping of the C-terminal β-strand only. A trimeric domain-swapped barnase was obtained at low pH and high protein concentration. Crystallographic studies revealed a structure suggesting a probable folding intermediate. Domain swapping was described for the cell cycle regulatory protein p13suc1, a small protein of 113 amino acids.

Folding studies as well as molecular dynamics simulations have shown that domain swapping occurs in the unfolded state. Eisenberg and his colleagues have proposed a free energy diagram for the pathway of domain swapping. The free energy difference between the closed monomer and domain-swapped oligomer is small since they share the same structures except at the hinge loop, but the energy barrier can be reduced under certain conditions making domain swapping more favorable. Several molecular or environmental events may favor the formation of extended domain-swapped polymers. Genetic mutations introducing a deletion in the hinge loop can destabilize the monomeric form of a protein. The replacement of only one amino acid can also favor the polymerization of the mutated protein. Three-dimensional domain-swapped oligomers are expected to be increasingly favored as the protein concentration increases. Thus, a metabolic change that increases the concentration of a protein will favor aggregation. Charge effects, caused either by mutations or by pH change or salt concentration, can induce domain swapping; for example, in RNase A, a decrease in pH, by protonating the residues involved in hydrogen bonds and in salt bridges, lowers the energy barrier of the formation of the open monomer, hence inducing domain swapping.

There is great diversity of swapped domains, with different sizes and sequences. They can consist of entire tertiary domains or smaller structural elements made of several residues. No specific sequence motif seems to be involved among the swapped domains. Three-dimensional domain swapping has also been proposed as a mechanism for amyloid formation. This aspect will be discussed in Sect. 4.2.

As can be seen here, several mechanisms exist, which lead to the formation of aggregates. It is recognized that aggregation results from the association of incompletely or incorrectly folded intermediates through hydrophobic interactions. In the energy landscape of protein folding, the presence of local minima separated by an energy barrier allows the accumulation of intermediates. If the barrier is high enough, these intermediates cannot easily reach the native state, and kinetic competition thus favors the formation of aggregates.

3
Protein Folding in the Cellular Environment

3.1
Molecular Crowding in the Cells

The main rules of protein folding have been deduced from a considerable body of *in vitro* and *in silico* studies. It has been accepted that the same mechanisms are involved in *in vitro* refolding and in the folding of a nascent polypeptide chain in the cell. However, the intracellular environment differs markedly from that of the test tube where low protein concentrations are used. The interior of a cell is highly crowded with macromolecules. The concentration is so high that a significant proportion of the volume is occupied. As mentioned by Ellis, in general, 20 to 30% volume of the interior of the cells are occupied by macromolecules; for example, the concentration of total protein inside cells ranges from 200 to 300 g L^{-1}. The total concentration of proteins and RNA inside *Escherichia coli* ranges from 300 to 400 g L^{-1} depending on the growth phase. Polysaccharides also contribute to the crowding. It can be predicted practically that diffusion coefficients will be reduced by factors up to 10-fold due to crowding. Since the average time for a molecule to move a certain distance varies by D^{-2}, D being the diffusion coefficient, it will take 100 times longer to move this distance in the cell as would be necessary under low concentration conditions. Another prediction indicates that equilibrium constants for macromolecular associations may be increased by two to three orders of magnitude.

Molecular crowding inside cells also has consequences for protein folding, favoring the association of partly folded polypeptide chains into aggregates. This could explain why cells contain molecular chaperones, even though most denatured proteins refold spontaneously in the test tube.

3.2
The Role of Molecular Chaperones

The discovery of a ubiquitous class of proteins mediating the correct folding in cellular environment has led to a reconsideration of the mechanism of protein folding *in vivo*. Historically, the term *molecular chaperone* was introduced by Laskyard and coworkers in 1987 to describe the function of nucleoplasmin, which mediates the *in vitro* assembly of nucleosomes from separated histones and DNA. The concept was further extended by Ellis to define a class of proteins whose function is to ensure the correct folding and assembly of proteins through a transient association with the nascent polypeptide chain. Studies on heat-shock proteins have widely contributed to the development of this concept.

Today, more than 20 protein families have been identified as molecular chaperones. Molecular chaperones comprise

several highly conserved families of related proteins. They can be divided into two classes according to their size. Small chaperones are less than 200 kDa, whereas large chaperones are more than 800 kDa. During the past few years, a large amount of biochemical, biophysical, and low- and high-resolution structural data have provided mechanistic insights into the machinery of protein folding as assisted by molecular chaperones.

Molecular chaperones are involved in diverse cellular functions. The constitutive members of the heat-shock protein family (Hsp70) can stabilize nascent polypeptide chains during their elongation in ribosomes. The large cylindrical chaperonins GroEL in bacteria, mitochondria, and chloroplasts and the corresponding TriC in eukaryotes and archaebacteria provide a sequestered environment for productive folding. Several chaperones are stress-dependent; their expression is induced under conditions such as high temperatures, which provoke protein unfolding and aggregation. The members of the Hsp90 and Hsp100 families, as well as small Hsp, play a role in preventing protein aggregation under stress. Chaperone interactions are also important for the translocation of polypeptide chains into membranes.

Within cells, the nascent polypeptide chain is synthesized sequentially on the ribosome by a vectorial process. For many proteins, the rate of this process is slower than the rate of folding. Synthesis times range from 20 s for a 400 residue–polypeptide chain in *E. coli* at 37 °C to 10 times as long for such a chain in an eukaryotic cell. Many unfolded proteins refold completely in 20 s under the same conditions. Thus, there is the possibility for the elongating polypeptide either to misfold before completion or to be degraded by proteolytic enzymes. Chaperones prevent such unfavorable events by protecting the nascent chain. Hsp70 and its prokaryotic homolog DnaK recognize extended hydrophobic regions of the elongating polypeptides. These interactions are not specific. Hsp70 and DnaK interact with most unfolded polypeptide chains that expose hydrophobic residues. They do not recognize folded proteins. Binding and release of unfolded proteins from Hsp70 are ATP-dependent and require the presence of various cochaperones such as DnaJ and GrpE. The basic mechanism of Hsp70 (DnaK in *E. coli*) is represented in Fig. 6. In *E. coli*, DnaJ binds the nascent unfolded polypeptide, U; then the complex binds to the ATP-bound state of DnaK. ATP is hydrolyzed in the ternary complex

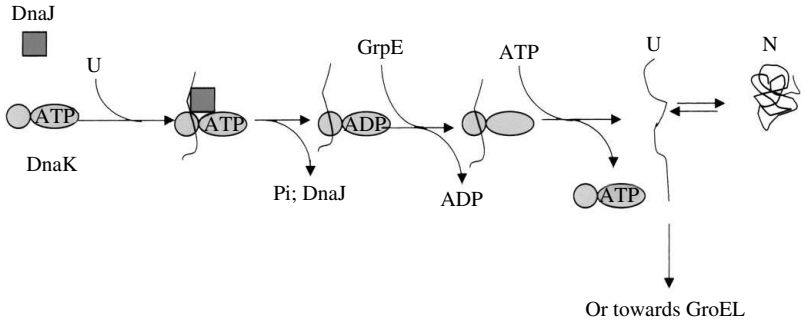

Fig. 6 Schematic representation of the basic mechanism of DnaK (see text).

allowing the release of DnaJ and P_i. In the following step, GrpE acts as an exchange factor to regenerate the ATP-bound state of DnaK. The unfolded polypeptide chain is released into the bulk solution. Thus, Hsp70 systems bind and release the polypeptide in an unfolded conformation. The unfolded protein has the possibility either to fold or to be transferred to the GroEL system, as illustrated in Fig. 6. Significant insights into this mechanism were obtained from structural data. The three-dimensional structures of Hsp70 and DnaJ as well as those of a complex DnaK–polypeptide and a complex of GrpE with the ATP binding domain of DnaK are known. DnaK and its homologs are composed of two domains, a C-terminal domain that binds ATP and an N-terminal domain that binds peptides. GrpE is a tight homodimer associated along two long helices. It binds DnaK–ATPase domain through its proximal monomer. DnaJ activates the ATP hydrolysis by DnaK. It was shown that a conformational change may occur upon ATP binding, opening the polypeptide binding cleft in the polypeptide binding domain of DnaK. The closed state may correspond to the ADP-bound conformation. The ADP-bound state of DnaK binds the peptide tightly. Peptide release requires the dissociation of ADP, which is mediated by GrpE. DnaK then rebinds ATP.

The GroEL–GroES system acts by a different mechanism in which the unfolded protein is sequestered. The chaperonins are large cylindrical protein complexes. The crystal structure of *E. coli* chaperonin GroEL was determined in 1994 and that of the asymmetric GroEL–GroES–(ADP)7 complex in 1997 by Sigler and his group. GroEL consists of two heptameric rings of 58-kDa subunits stacked back to back with a dyad symmetry and forming a porous cylinder (Fig. 7). Each subunit is organized in three structural domains. A large equatorial domain forms the foundation of the assembly and holds the rings together. It contains the nucleotide binding site. A large apical domain forms the end of the cylinder. The apical domain contains a number of hydrophobic

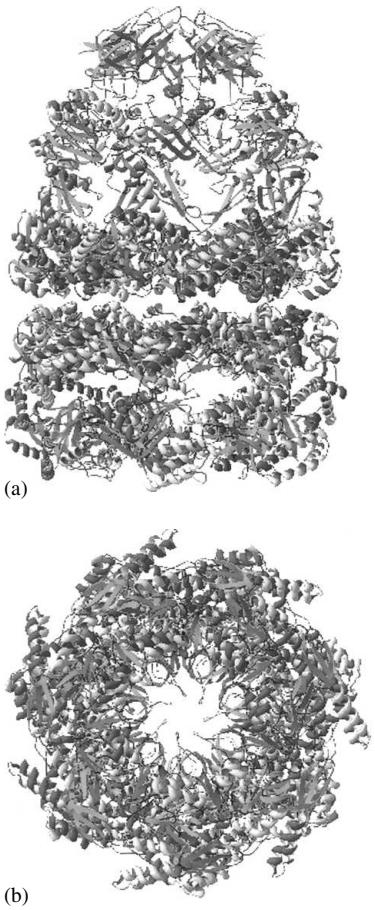

Fig. 7 Crystal structure of GroEL–GroES–(ADP)7 complex determined by Sigler et al. (a) view along the axis and (b) view from the top of the complex. (Reproduced from the PDB web site.)

residues exposed to the solvent. A small intermediate domain connects the two large domains. The intermediate segments have some flexibility allowing a hinge-like opening of the apical domains, which occurs upon nucleotide binding. These movements are large and have been visualized by three-dimensional reconstruction from cryoelectron microscopy by Sebil and her group.

GroES is a heptamer of 10 kDa subunits forming a flexible dome-shaped structure with an internal cavity large enough to accommodate proteins up to 70 kDa. Each subunit is folded into a single domain containing β-sheets and flexible loop regions. The loop regions are critical for the interactions between GroEL and GroES. It was deduced from electron microscopy studies that GroES binding to GroEL induces large movements in the apical GroEL domains. This provokes a significant increase in the volume of the central cavity in which protein folding proceeds. NMR coupled with the study of hydrogen-exchange techniques has indicated that small proteins are essentially unfolded in their GroEL-bound states. Mass spectroscopy has revealed the presence of fluctuating elements of secondary structure for several proteins. In a way, the GroEL–GroES system recognizes nonnative proteins.

The reaction cycle of the GroEL–GroES system is represented in Fig. 8. The nonnative protein binds to the apical domain of the upper ring of GroEL through hydrophobic interactions. Then, the equatorial domain of the same ring binds ATP, and GroES caps the upper ring, sequestering the protein inside the internal chamber in which the protein folding proceeds. The binding of GroES induces a conformational change in GroEL and ATP hydrolysis, which is a cooperative process that produces a conformational change in the lower ring, allowing it to bind a nonnative protein molecule. This promotes subsequent binding of ATP and GroES in the lower ring, and the dissociation of the upper complex, releasing the protein and ejecting GroES. If the protein has not reached the native state, it is subjected to a new cycle.

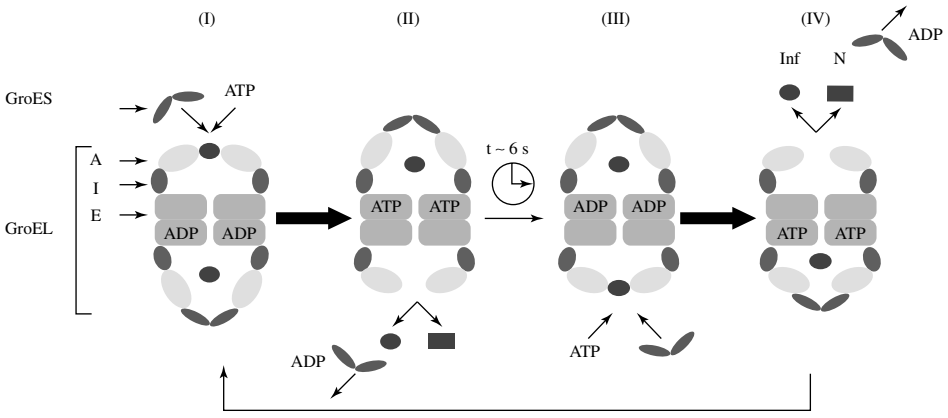

Fig. 8 The reaction cycle of GroEL–GroES. Inf is the unfolded protein, N the folded one, A is the apical domain, (in blue), I the intermediate domain (in red) and E the equatorial domain (in magenta). (Reproduced from Wang & Weissman (1999) *Nat. Struct. Biol.* **6**, 597, with permission.) (See color plate p. xxii).

The hydrolysis of ATP by GroEL is used only to induce conformational changes of the chaperone, which permits the release of the folded protein. The molecular chaperones, by their transient association through hydrophobic interactions with nascent, stress-destabilized, or translocated proteins, have a role in preventing improper folding and subsequent aggregation. They do not interact with folded proteins. They do not carry information capable of directing a protein to assume a structure different from that dictated by its amino acid sequence. Therefore, molecular chaperones assist the folding in the cells without violation of the Anfinsen postulate. They increase the yield but not the rate of folding reactions; in this respect they do not act as catalysts. Furthermore, the majority of newly synthesized polypeptide chains in both bacterial and eukaryotic cells fold spontaneously without the assistance of molecular chaperones.

Many proteins from prokaryotic and eukaryotic organisms are produced with an amino-terminal propeptide, which is removed by limited proteolysis during the activation process. Several of these propeptides consist of a long polypeptide chain; for example, there are 174 amino acids in the propeptide of pro-α-lytic protease, 91 in that of procarboxypeptidase Y, and 77 in that of prosubtilisin. Several studies have shown that the propeptide is required for proper folding of these proteins. The mature enzymes are not able to refold correctly. They seem to have kinetic stability only, whereas the proenzymes have thermodynamic stability. Since propeptides perform the function of mediating protein folding, they have been classified as intramolecular chaperones. However, this terminology is not appropriate since the nascent protein is the proenzyme, not the enzyme that has undergone proteolytic cleavage. Thus, it is not surprising that the proenzyme refolds spontaneously, whereas the mature protein does not. Indeed, the information is contained in the totality of the proenzyme sequence.

Two other classes of proteins play the role of helpers during protein folding *in vivo*: protein disulfide isomerases (PDIs) and peptidyl–prolyl cis – trans isomerases. Protein disulfide isomerase is an abundant component of the lumen of the endoplasmic reticulum in secretory cells. The enzyme was discovered independently in 1963 by two research groups: in rat and ox by Anfinsen and coworkers, and in chicken and pigeon pancreas by Straub and coworkers. Proteins destined to be secreted enter the endoplasmic reticulum in an unfolded state. In this environment, the folding process is associated with the formation of disulfide bonds, which is catalyzed by PDI through thiol–disulfide interchange. The first PDI cDNA was sequenced in 1985 by Edman et al. It displays sequence homologies implying a multidomain architecture. PDI consists of four structural domains arranged in the order a, b, b′, a′, with the b′ and a′ domains being connected by a linker region. Furthermore, it possesses an acidic C-terminal extension. The a and a′ domains contain the active site motif – W-C-G-H-C-. They display significant sequence identity to thioredoxin, a small cytoplasmic protein involved in several redox functions, and they have a similar active site sequence.

Recombinants of the a and b domains have been obtained and studied by high-resolution NMR. The a domain has the same overall fold as thioredoxin, an α/β fold with a central core made up of a five-stranded β-sheet surrounded by four helices. As in thioredoxin, the active site is located at the N-terminus of helix

α_2. Preliminary NMR data of the a′ domain confirm its structural similarity to the a domain. The b and b′ domains have significant sequence similarity to each other, but no similarity with the a domain. Nevertheless, NMR studies of the b domain have indicated a similar overall fold. From its sequence, it could be inferred that b′ also has the same fold. Neither b nor b′ contain the active site.

The folding pathway of disulfide-bound proteins involves isomerizations between a number of species containing disulfide bonds. *In vitro* experimental studies were performed using the isolated a and a′ domains, and the results were compared with those obtained with the holoenzyme. It was concluded that the activity of long length PDI is not simply the sum of the activities of the isolated a and a′ domains. Using a series of constructs including nearly every linear combination of domains, the contribution of each domain was investigated. It was determined that the thiol-disulfide chemistry requires only the a and a′ domains, and that simple isomerization requires one of these in a linear combination including b′, whereas complex isomerization involving large conformational changes requires all the PDI domains except the C-terminal extension. Thus, it appears that the b′ domain is the principal peptide binding site, but all domains contribute to the binding of larger polypeptide chains holding them in a partially unfolded conformation while the catalytic sites acts synergistically to perform the thiol-disulfide exchange. Since PDI has binding properties, it has been proposed that it acts as a molecular chaperone. However, as underlined by Freedman and coworkers, this property does not represent a chaperone activity and instead reflects its role as a catalyst to accelerate the formation of native disulfide bridges during protein folding.

Several gene products with similarity to PDI have been identified in higher eukaryotes. All are probably localized in the endoplasmic reticulum and have thiol-disulfide exchange activity.

In prokaryotes, the disulfide formation occurs in the periplasm and is catalyzed by a protein called DsbA, which exchanges its Cys30–Cys33 to a pair of thiols in the target protein, leaving DsbA in its reduced state. The crystal structure of oxidized DsbA displays a domain with a thioredoxin-like fold and another domain, which caps the thioredoxin-like active site C30-P31-H32-C33, located at the domain interface. Reoxidation of DsbA is catalyzed by a cytoplasmic membrane protein called DsbB, which contains four cysteine residues essential for catalysis. DsbB transfers the electrons from the reduced DsbA to membrane embedded quinones. The reduced quinones are then oxidized enzymatically either aerobically or anaerobically. Thus, DsbA is found in normal cells in its oxidized state. *E. coli* also has a complex reductive system including another periplasmic protein DsbC, which is a homodimer. The molecule consists of two thioredoxin-like domains with a CxxC motif, joined via hinged linker helices to an N-terminal dimerization domain. The hinge regions allow movement of the active site, and a broad hydrophobic cleft between the two domains may bind the polypeptide chain. Its function consists of reducing proteins with incorrect disulfide bonds. DsbC is maintained in its reduced form by a membrane protein called DsbD, which contains six essential cysteine residues. Then, the electrons are transferred to thioredoxin and ultimately to NADPH by thioredoxin reductase.

All these enzymes, which catalyze the pairing of cysteine residues in disulfide-bridged proteins, have functional domains pertaining to the thioredoxin superstructure.

Another type of enzyme, peptidyl–prolyl cis–trans isomerases, facilitates the folding of some proteins by catalyzing the cis–trans isomerization of X-Pro peptide bonds. Two classes of unrelated proteins demonstrate this activity, those that bind cyclosporin, which are known as *cyclophilins*, and those that bind FK506. The cellular function of these enzymes is important, since cyclosporin and FK506 are potent immunosuppressors that regulate T-cells activation. Both classes of peptidyl–prolyl isomerases are ubiquitous, and abundant in prokaryotes and eukaryotes. The sequences of several members of each family are known, and the three-dimensional structures of at least one member of each family have been elucidated by X-ray crystallography and multidimensional NMR. Their role is to accelerate the cis-trans isomerization of X-pro peptide bonds when this process is the rate-limiting step in protein folding. Although they do not present structural similarity, both exhibit a hydrophobic binding cleft favoring the rotamase activity by excluding water molecules.

4
Protein Aggregation in the Cellular Environment

4.1
The Formation of Inclusion Bodies

The overexpression of genes introduced in foreign hosts frequently results in aggregated nonnative proteins called *inclusion bodies*. In cells, inclusion bodies appear as unordered amorphous aggregates clearly separated from the rest of the cytoplasm; they form a highly refractive area when observed microscopically. A great variety of experimental studies indicates that the formation of inclusion bodies results from partially folded intermediates in the intracellular folding pathway and not from either totally unfolded or native proteins.

4.1.1 Occurrence of Inclusion Bodies

Inclusion bodies were first identified in the blood cells of patients with abnormal hemoglobins, the resulting pathology being anemia. Pathological point mutants of hemoglobin aggregate into inclusion bodies; this is the case for hemoglobin Köln (Val98Met on the β chain) and hemoglobin Sabine (Leu91Pro on the β chain). Similar deposits have been described in studies on the metabolism of abnormal proteins subjected to covalent modification in *E. coli*. The formation of aggregates also occurs when cells are subjected to heat shock.

The *in vivo* folding pathway of tailspike endorhamnosidase of Salmonella phage 22 is a well-documented system studied by J.King's group. Furthermore, it is one of the few systems in which the *in vivo* folding pathway has been compared with the *in vitro* refolding pathway. The protein is a trimer of 666 amino acids. The secondary structure is predominantly β-sheet. Newly synthesized polypeptide chains released from the ribosome generate an early partially folded intermediate. This intermediate further evolves into a species sufficiently structured for chain–chain recognition. In the following step, an incompletely folded trimer is formed upon close association with the latter species. The protrimer is then transformed into the native tailspike. A clear difference between the physicochemical properties of the intermediates and the native state has

allowed their identification. Figure 3 illustrates the folding pathway of the protein. The native protein is highly thermostable with a T_m of 88 °C; it is also resistant to detergents and proteases. During the *in vivo* folding process, the intermediates are sensitive to these factors, allowing their identification. At low temperature, almost 100% of the newly synthesized chains reach the native trimer conformation. When the temperature increases in the cells, the number of polypeptide chains achieving the native state decreases. At 39 °C, the maturation proceeds with 30% efficiency, while the remainder aggregates into inclusion bodies. It has been shown that the aggregation does not result from an intracellular denaturation of the native protein, but is generated from an early thermolabile intermediate. The aggregated chains cannot recover their proper folding by lowering the temperature. But when polypeptide chains that have been synthesized at high temperatures are shifted to low temperature early enough, they can refold correctly.

A set of mutations that alter protein folding without modifying the properties and stability of native P22 tailspike has been identified; they are referred to as temperature-sensitive folding (tsf) mutants. These mutations have been supposed to destabilize the already thermolabile intermediate and are located at more than 30 sites in the central region of the polypeptide chain. Starting from mutants kinetically blocked in their folding, a second set of mutants capable of correcting the folding defects was selected, and the sequences surrounding the suppressor mutations were identified. Only two substitution positions on the 666 amino acids of the polypeptide chain were sufficient to prevent inclusion body formation. Thus, single temperature mutations that affect the folding pathway but not the native conformation of a protein are efficient in preventing off-pathway and subsequent aggregation. A similar result has been found for heterodimeric luciferase. For recombinant proteins such as interferon-γ and interleukin 1β, as well as for P22 tailspike, amino acid substitutions that can decrease or increase the formation of inclusion bodies without alteration of the functional structure were found by Wetzel and coworkers.

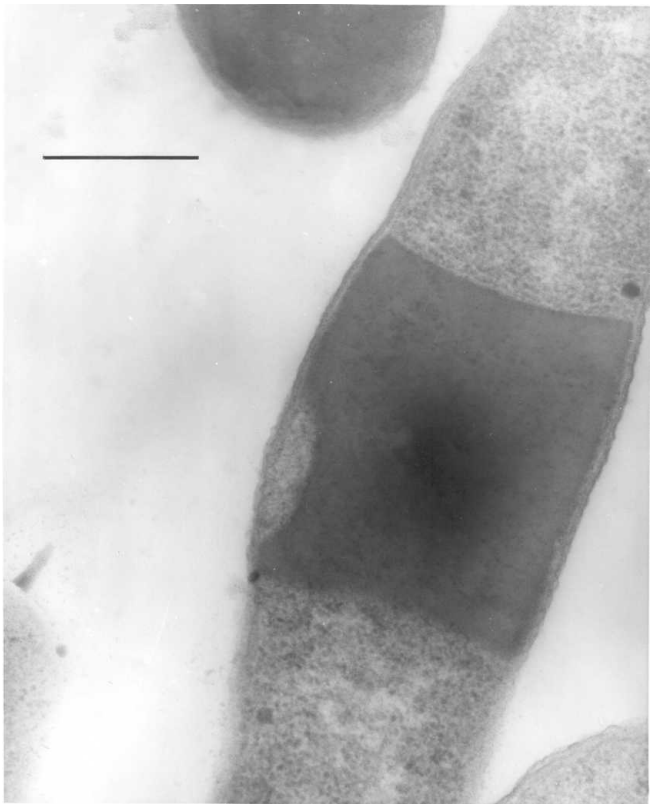
The formation of inclusion bodies is frequently observed in the production of recombinant proteins. High levels of expression of these proteins result in the formation of inactive amorphous aggregates, and has been reported for proteins expressed in *E. coli* and also in several host cells, gram-negative as well as gram-positive bacteria, and eukaryotic cells such as *Saccharomyces cerevisiae*, insect cells, and even animal cells. The production of recombinant proteins, among them human insulin, interferon-γ, interleukin 1β, β-lactamase, prochymosin, tissue plasminogen activator, basic fibroblast growth hormone, and somatotropin, gives rise to inclusion bodies.

4.1.2 Characteristics of Inclusion Bodies

Inclusion bodies can form in the cytoplasm and in the periplasmic space of *E. coli*. Wild-type β-lactamase expressed in *E. coli* results in the formation of inclusion bodies in the periplasm, whereas the protein expressed without its signal sequence aggregates in the cytoplasm.

The characteristics of the aggregates depend on how the protein is expressed. Different sizes and morphologies have been observed. Generally, inclusion bodies appear as dense isomorphous aggregates of nonnative proteins separated from the rest of the cytoplasm, but not surrounded

(a)



(b)

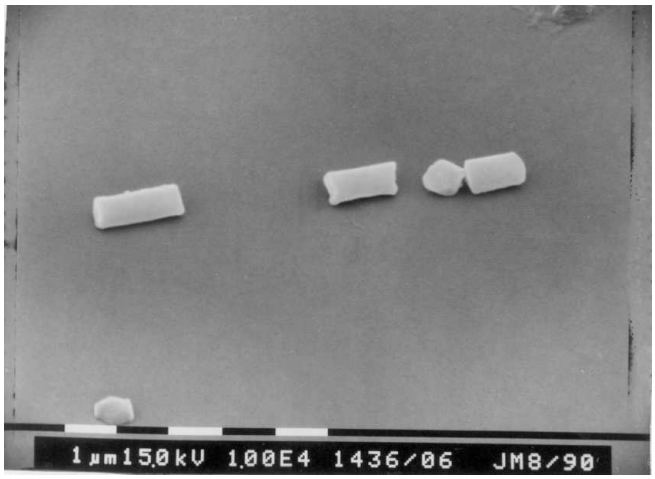


Fig. 9 Electron micrographs of (a) cytoplasmic β-lactamase inclusion bodies in *E. coli* RB791 (pGB1) and (b) purified inclusion bodies from the same origin (courtesy of G.A. Bowden, A.M. Paredes & G. Georgiou).

by a membrane (Fig. 9). They look like refractile inclusions, which can be easily recognized by phase contrast microscopy when large enough. For prochymosin expressed in *E. coli*, the lack of birefringence indicates that inclusion bodies are not crystalline. The size distribution of inclusion bodies has been studied for prochymosin and interferon-γ, and Marston reported the mean size of particles to be 0.81 and 1.28 μm respectively, with a relatively high void fraction. The void volume was about 70% of the total volume for interferon-γ and 85% for prochymosin. Structural characterization studies using ATR-FTIR (attenuated total reflectance Fourier transformed infrared spectroscopy) have shown that the insoluble nature of inclusion bodies may be due to their increased levels of nonnative intramolecular β-sheet content.

Inclusion bodies consist mostly of the overexpressed recombinant protein, and can contain little contaminating molecules. Thus, they can be used as a source of relatively pure misfolded protein when refolding yields the active protein. However, some amorphous bodies incorporate other molecules, for example, inclusion bodies from *E. coli* cells overexpressing β-lactamase contain only between 35 and 95% intact β-lactamase. The rest consists of a variety of intracellular proteins, some lipids, and a small amount of nucleic acids. Homogeneous inclusion bodies were obtained by expressing β-lactamase without its leader peptide. Under these conditions, aggregation occurs within the cytoplasm. The extent of incorporation of other macromolecules in inclusion bodies depends upon the overexpressed protein.

The formation of inclusion bodies generally appears to be a disadvantage, since it requires the dissolving of the aggregates in denaturant and subsequent refolding of the protein. However, when the recovery of the active product can be obtained with a sufficient yield, certain advantages may accrue. Indeed, aggregation generally prevents proteolytic attack, except when the protein coaggregates with a protease. The formation of inclusion bodies is also an advantage for the production of proteins that are toxic for the host cells. Furthermore, these aggregates contain a great quantity of the overexpressed protein.

4.1.3 Strategies for Refolding Inclusion Body Proteins

The recovery of the active protein from inclusion bodies is crucial for industrial purposes. In structural proteomics today, efficient production of genetically engineered proteins is a prerequisite for exploiting the information contained in the genome sequences. The strategy to recover active proteins involves several steps of purification. The first step, the separation of the inclusion bodies from the cell, consists of cell lysis monitored either by high-pressure homogeneization, or by a combination of mechanical, chemical, and enzymatic techniques such as the use of EDTA and lysozyme. The lysates are then treated by low-speed centrifugation or filtration to remove the soluble fraction from the pellet containing inclusion bodies and cell debris. The most difficult task is to remove the contaminants; this is achieved by the washing steps, which commonly utilize EDTA and low concentrations of denaturants or detergents such as Triton X-100, deoxycholate, or octylglucoside. Using centrifugation in a sucrose gradient, it is generally possible to remove cell debris and membrane proteins. When the accumulation levels of aggregates are very high, inclusion bodies may be directly solubilized by treatment in a high concentration of denaturant, eliminating the need for gradient centrifugation. In this

case, the costs of production are considerably reduced.

A variety of techniques are available to solubilize purified inclusion bodies. The most commonly used solubilizing reagents are strong denaturants such as guanidine hydrochloride and urea. Generally, high denaturant concentrations are employed, 4 to 6 M for guanidine hydrochloride, and 5 to 10 M for urea to allow the disruption of noncovalent intermolecular interactions. Conditions may differ somewhat according to the denaturant and the protein. Lower denaturant concentrations have been used to solubilize cytokines from *E. coli* inclusion bodies. The purity of the solubilized protein was much higher at 1.5 to 2 M guanidinium chloride than at 4 to 6 M guanidinium chloride. At higher denaturant concentrations, contaminating proteins were also released from the particulate fractions.

Extremes of pH have also been used to solubilize inclusion bodies and for growth hormone, proinsulin, and some antifungal recombinant peptides. However, exposure to very low or very high pH may not be applicable to many proteins and may cause irreversible chemical modifications.

Detergents such as sodium dodecylsulfate (SDS) and n-cetyl trimethylammonium bromide (CTAB), have also been used to solubilize inclusion bodies. Extensive washing may then be needed to remove the solubilizing detergents. They also may be extracted from the refolding mixture by using cyclodextrins, linear dextrins, or cycloamylose. Recent developments include the use of high hydrostatic pressure (1–2 kbar) for solubilization and renaturation. For proteins with disulfide bonds, the addition of a reducing reagent such as dithiothreitol or β-mercaptoethanol is necessary to disrupt the incorrectly paired disulfide bonds. The concentrations generally used are 0.1 M for dithiothreitol and 0.1 to 0.3 M for β-mercaptoethanol.

When expression levels are very high, an *in situ* solubilization method can be used. It consists of adding the solubilizing reagent directly to the cells at the end of the fermentation process. The main disadvantage of this technique concerns the release of contaminants.

The last step is the recovery of the active protein. When inclusion bodies have been solubilized, the refolding is achieved by removal of the denaturant. This can be done by different techniques including dilution, dialysis, diafiltration, gel filtration, chromatography, or immobilization on a solid support. Dilution has been extensively used. It considerably reduces concentrations of both denaturant and protein. This procedure, however, cannot be applied to the commercial scale refolding of recombinant proteins, because large downstream processing volumes increase the cost of products. Although dialysis through semipermeable membranes has been used successfully to refold several proteins, it is not employed in large-scale processes. This is because it requires very long processing times, and there is the risk that during dialysis, the protein will remain too long at a critical concentration of denaturant and aggregate. The removal of the denaturant may be accomplished through gel filtration. However, here again, a possible aggregation could lead to flow restriction within the column. Dialfiltration through a semipermeable membrane allows the removal of denaturant and other small molecules and retains the protein. This procedure has been used for large-scale processing and was particularly efficient in the refolding of prorennin and interferon-β.

During the refolding process, the formation of incorrectly folded species and aggregates usually decreases the refolding yield. For disulfide-bridged proteins, the renaturation buffer must contain redox-shuffling mixture to allow the formation of correctly paired disulfide bridges. Stabilizing reagents may be added to improve the refolding yield. An efficient strategy is the addition of small molecules to suppress intermolecular interactions leading to aggregation. Sugar, alcohols, polyols (including sucrose, glycerol, polyethylene glycol, isopropanol), cyclodextrin, laurylmaltoside, sulfobetains, L-arginine, and low concentrations of denaturants and detergents, have been used to increase the refolding yield. L-arginine at a concentration ranging from 0.4 M to 0.8 M is the most widely used additive today.

Another important factor in the refolding process is the rate of removal of the denaturant. Since there is kinetic competition between the correct folding and the formation of aggregates from a folding intermediate, conditions that favor folding over the accumulation of aggregates must be found. To optimize this selection, Vilick and de Bernadez–Clark developed a strategy for achieving high protein refolding yields. They start from a model of refolding, develop the equations of refolding kinetics, characterize the rate-limiting step of the process, determine the influence of various environmental parameters, and finally optimize the system of equations in a scheme involving diafiltration to remove the denaturant. The approach was evaluated in the refolding of carbonic anhydrase from 8 M urea. The yield obtained after three diafiltration experiments was 69% whereas the model predicted a yield of 73%.

The properties of molecular chaperones have also been utilized to increase the refolding yield. Altamiro and coworkers have developed a system for refolding chromatography that utilizes GroEL, DsbA, and peptidyl–prolyl isomerase immobilized on an agarose gel. Kohler and coworkers have built a chaperone-assisted bioreactor; however, it could only be used for three cycles of refolding and needs to be improved. Another strategy consists of the co-overproduction of the DnaK–DnaJ or GroEL–GroES chaperones with the desired protein; this can greatly increase the soluble yield of aggregation-prone proteins. Fusion proteins have also been used to minimize aggregation.

The recovery of active proteins from inclusion bodies is a rather complex process. Although some general strategies have been developed, optimal conditions have to be determined for each protein. Recently, genetic strategies to improve recovery processes for recombinant proteins have been introduced. They consist of the introduction of combinatorial protein engineering to generate molecules highly specific to a particular ligand. Such methods, which allow efficient recovery of a recombinant protein, will be increasingly used in industrial scale bioprocesses as well.

4.2 The Formation of Amyloid Fibrils and its Pathological Consequences

The formation of amyloid fibrils plays a key role in the origin of several neurodegenerative pathologies, such as spongiform encephalopathies and Alzheimer's disease. Historically, the term amyloid was introduced to describe fibrillar protein deposits associated with diseases known as *amyloidoses* that involve the extracellular deposition of amyloid fibrils and plaques with the aspect of starch. For many of these diseases, the major fibrillar

protein component has been identified. In the 1970s, it was demonstrated that lysosomal proteins under acidic conditions could form amyloid fibrils. It was generally accepted at this time that proteolysis was the amyloidogenic determinant. Twenty years later, it was shown that purified transthyretin is converted into amyloid fibrils via an acid-induced conformational change *in vitro*, demonstrating that conformational changes alone were responsible for producing an intermediate generating amyloid structure. These aberrant protein self-assemblies are at the origin of more than hundred human amyloid diseases, some of them being lethal.

Twenty unrelated protein precursors are known to form amyloid fibrils, among them transthyretin, lysozyme, immunoglobulin light chain, β_2 microglobulin, Alzheimer Aβ1–40 and Aβ1–42 peptides, the mammalian prion protein, and the yeast prion-like proteins (Table 1). Since they are subjects of another chapter, prion proteins will not be discussed here. Although they have no homology in sequence and structure, all form amyloid fibrils with a similar overall structure, suggesting a common self-assembly

Tab. 1 Amyloidogenic proteins and the corresponding diseases.

Clinical syndrome	*Precursor protein*	*Fibril component*
Alzeimer's disease	APP	β-peptide 1–40 to 1–43
Primary systemic amyloidosis	Immunoglobulin light chain	Intact light chain or fragments
Secondary systemic amyloidosis	Serum amyloid A	Amyloid A (76-residue fragment)
Senile systemic amyloidosis	Transthyretin	Transthyretin or fragments
Familial amyloid polyneuropathy I	Transthyretin	Over 45 transthyretin variants
Hereditary cerebral amyloid angiopathy	Cystatin C	Cystatin C minus 10 residues
Hemodialysis-related amyloidosis	β_2-microglobulin Apolipoprotein A1	β_2-microglobulin Fragments of Apolipoprotein A1
Familial amyloid polyneuropathy III	Gelsosin	71-amino acid fragment of gelsosin
Finnish hereditory systemic amyloidosis	Islet amyloid polypeptide (IAPP)	Fragment of IAPP
Type II diabetes Medullary carcinoma of the thyroid	Calcitonin	Fragments of calcitonin
Spongiform encephalopathies	Prion	Prion or fragments thereof
Atrial amyloidosis	Atrial natriuretic factor (ANF)	ANF
Hereditary nonneuropathic systemic amyloidosis	Lysozyme	Lysozyme or fragments thereof
Injection-localized amyloidosis	Insulin	Insulin
Hereditary renal amyloidosis	Fibrinogen	Fibrinogen fragments
Parkinson disease	α-synuclein*

pathway. In all proteins known to form amyloid fibrils, there is a conversion of α- to β-structure. Amyloid fibrils are abnormal, insoluble, and generally protease-resistant structures. They were first recognized by their staining properties. The most commonly used method to detect amyloid is staining by Congo Red, which exhibits a green birefringence. Amyloid fibrils are generally 60 to 100 Å in diameter and of variable length. X-ray diffraction data on fibrils, solid-state NMR studies, cryoelectron microscopy, and infrared Fourier transform experiments have shown that amyloid fibrils are made of two or more β-sheet filaments wound around one another. They have a characteristic cross-β repeat structure, the individual β-strands being oriented perpendicular to the long axis of the fibril.

Recently, progress has been made in the knowledge of the mechanisms involved in the formation of amyloid fibrils. Oligomeric prefibrillar intermediates have been extensively characterized with respect to their structure and temporal evolution. A well-documented example is provided by the studies on transthyretin. The biological role of this protein is the transport of thyroxin by direct binding and the transport of retinol via the retinol binding protein. The wild-type protein is very stable at neutral pH. In certain individuals, however, it is converted into amyloid fibrils, and this is associated with the disease, senile systemic amyloidosis. Several variants are associated with familial polyneuropathies. *In vitro* biophysical studies have identified conditions leading to amyloid formation. The three-dimensional structure of the protein is known. The wild-type protein is a tetramer at pH ranging between 5 and 7; the tetramer dissociates into a monomer when the pH decreases. The dissociation is the rate-limiting step of the process. The monomer exhibits an altered tertiary structure, which aggregates in amyloid

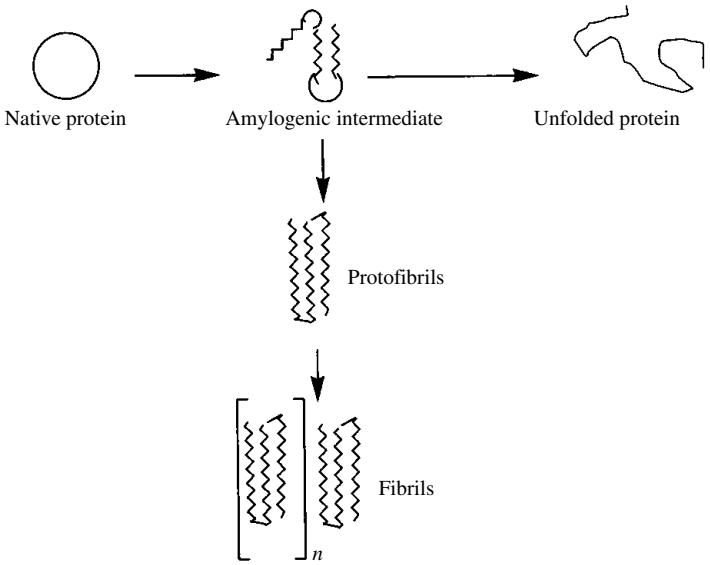

Fig. 10 Schematic representation of the formation of amyloid fibrils from a partially folded intermediate.

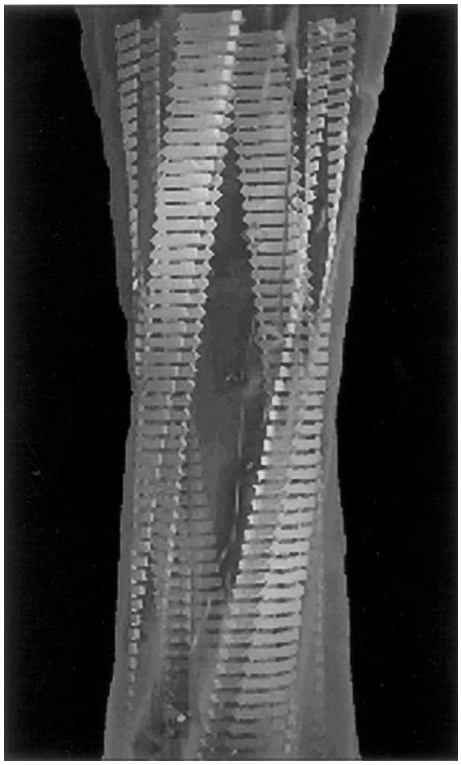
protofilaments, and then forms amyloid fibrils. This formation is at its maximum at pH 4.4. Using deuterium–proton exchange monitored by two-dimensional NMR spectroscopy on transthyretin at pH 5.75 and 4.5, Liu et al. have shown a selective destabilization of one half of the β-sandwich structure of the protein, increasing the mobility of this region. These studies have identified the residues that undergo increased conformational fluctuations under amyloidogenic conditions. The mutations in the pathological variants responsible for familial amyloid polyneuropathies are localized in this region. A strategy to delay the formation of amyloid fibrils proposed by Saccheti & Kelly was to develop molecules capable of stabilizing the tetramer.



Two variants of human lysozyme, Ile56Thr and Asp67His have been reported to be amyloidogenic; they are responsible for fatal amyloidoses. Pepys and colleagues have determined the precise structures and properties of these mutants. The native fold of the two amyloidogenic variants, as resolved by X-ray crystallography, is similar to that of the wild-type protein. Both variants are enzymatically active, but have been shown to be unstable. The replacement of an aspartate by a histidine suppresses a hydrogen bond formed in the wild-type protein with a tyrosine in a neighboring β-strand. This rupture opens a large gap between two β-strands. In the other variant, the replacement of an isoleucine by a threonine suppresses a van der Waals contact with a neighboring helix. Consequently, changes in the interface between the α- and β-domains occur in both variants, destabilizing the molecule.

The mutations leading to amyloid fibril formation are observed to result in a decreased stability of the native state. In all cases, the formation of fibrils occurs from a partially structured molecule via nucleation-dependent oligomerization. It was observed for several proteins that fibrillation takes place only after a lag phase, which is abolished upon seeding. Nucleation is followed by the formation of protofibrils whose characteristics have been determined (Fig. 10). Atomic force microscopy and fluorescence correlation spectroscopy have been used to monitor transitions among the different types of assemblies.

Fig. 11 Molecular model of an amyloid fibril derived from cryoelectron microscopy analysis of fibrils grown from an SH3 domain by incubation of a solution containing the protein at low pH (reproduced from Dobson, C. (1999) *TIBS* **24**, 331, with permission).

Recent observations from Dobson and his group have shown that several proteins unrelated to amyloid diseases are able to aggregate *in vitro* into amyloid fibrils when exposed to mild denaturing conditions. These fibrils are indistinguishable from those found in pathological conditions. It was demonstrated for different proteins such as normal lysozyme, an SH_3 domain of a phosphatidyl inositol protein kinase (Fig. 11), an acyl phosphatase, and an α-helical protein, myoglobin suggesting a common mechanism for the formation of amyloid. These findings clearly indicate that amyloid formation is a general property of polypeptide chains rather than one restricted to definite sequences as occurs with chameleon sequences capable of adopting either a β- or an α-helicoidal structure depending on their environment. Furthermore, these aggregates exhibited an inherent toxicity when incubated with mouse fibroblasts. Several groups suggest that oligomeric intermediates rather than fibrils themselves are responsible for pathogenicity.

Significant progress has been made in understanding the mechanisms involved in the formation of amyloid fibrils. This is an important step in guiding research into the discovery of molecules with therapeutic efficiency.

Keywords

Aging
The progressive impairments of functions experienced by many organisms throughout their life span.

DNA Damage
A DNA alteration that has an abnormal structure, which cannot itself be replicated when the DNA is replicated, but which may be repaired.

DNA Repair
The process of removing damage from DNA and restoring the DNA structure.

Mutation
A change in the sequence of DNA base pairs, which may be replicated and thus inherited.

Sex
The process by which genetic material (usually DNA) from two separate parents is brought together in a common cytoplasm where recombination of the genetic material ordinarily occurs, followed by the passage of the recombined genome(s) to progeny.

Complementation
The masking of the expression of mutant genes by corresponding wild-type genes when two homologous chromosomes share a common cytoplasm.

A number of theories have been proposed to account for the biological phenomena of aging and sexual reproduction (sex). An emerging unified theory that accounts for a considerable amount of the data relating to both aging and sex is presented here.

Aging appears to be a consequence of DNA damage, while sexual reproduction (sex) appears to be an adaptation for coping with both DNA damage and mutation. DNA, the genetic material of most organisms, is composed of molecular subunits that are not endowed with any peculiar chemical stability. Thus, DNA is subject to a wide variety of chemical reactions that might be expected of any such molecule in a warm aqueous medium. DNA damages are known to occur very frequently, and organisms have evolved enzyme-mediated repair processes to cope with them. In any cell, however, some DNA damage may remain unrepaired despite repair processes. Aging appears to be due to the accumulation of unrepaired DNA damage in somatic cells, especially in nondividing cells such as those in mammalian brain and muscle.

On the other hand, the primary function of sex appears to be the repair of damages in germ cell DNA through efficient recombinational repair when chromosomes pair during the sexual process. This allows a relatively undamaged genome to initiate the next generation. In addition, in diploid organisms, sex allows chromosomes from genetically unrelated individuals (parents) to come together in a common cytoplasm (that of progeny). Since genetically unrelated parents ordinarily would not have common mutations, the chromosomes present in the progeny should complement each other, masking expression of any deleterious mutations that might be present.

Thus, aging and sex appear to be two sides of the same coin. Aging reflects the accumulation of DNA damage and sex reflects the removal of DNA damage, and in diploid organisms, the masking of mutations by complementation.

1
The DNA Damage Theory of Aging

1.1
Occurrence of DNA Damage and Pathways of DNA Repair

Except for certain viruses with an RNA genome, the genomes of most organisms are composed of DNA. If DNA damage is the cause of aging, then DNA damage is expected to occur frequently in multicellular organisms. Table 1 lists some important types of DNA damage caused by normal metabolic processes in mammals. These data suggest, for instance, that in the rat at least 95,000 DNA damages of various types occur, averaged over all cell types, per cell per day. The majority of these damages alter the structure of only a single DNA strand, so the redundant information in the complementary strand can usually be used to repair the damage. The damages shown in Table 1 are the newly occurring damages, most being rapidly repaired.

Five major DNA repair pathways known to be utilized by cells to repair the damages indicated in Table 1 are as follows:

- Nucleotide excision repair (NER) [with two subpathways, largely using the same enzymes: transcription coupled repair (TCR) and global genomic repair (GGR)]
- Base excision repair (BER)
- Nonhomologous end joining (NHEJ)
- Homologous recombinational repair (HRR)
- O^6-methylguanine-DNA methyltransferase (MGMT)

1.2
Consequences of Unrepaired DNA Damage

If accumulated DNA damages are the cause of aging, then repair processes would be less than 100% efficient; some types of unrepaired damages left each day would gradually build up in nondividing or slowly dividing cells. Most investigators examining the presence of DNA damages in tissues of young versus old mammals (usually rodents) have found an accumulation of damaged bases or single- or double-strand breaks with age. The tissues where accumulation of DNA damage has been shown include liver, kidney, heart, muscle, and brain.

A number of different types of DNA damage have been tested for their effects on transcription and DNA replication. It was found that transcription is blocked by UV-induced damages (mainly pyrimidine dimers) by adducts produced by derivatives of benzo[a]pyrene, *N*-acetoxy-2-fluorenylacetamide, or aflatoxin B_1 and also by the oxidized base, thymine glycol. UV-induced DNA damages and thymine glycol have also been shown to block DNA replication. These findings suggest that many types of DNA damage inhibit transcription and replication.

A reduction in the ability to transcribe mRNA should lead to a decline in the function of the cells. In fact, in mammalian

Tab. 1 Endogenous DNA damages in mammalian cells.

Type of damage	*Approximate average incidence (DNA damages/cell/day)*
Oxidative	500,000 (young mouse brain) 2,000,000 (old mouse brain) 86,000 (rats, all tissues) 10,000 (humans, all tissues)
Depurinations	9,000 (humans and rats)
Single-strand break	7,200 (*in vitro*)
O^6-methylguanine	2,000 (*in vitro*)
Double-strand break	>40 (rats)[a] >3 (humans)[a]
DNA cross-link	>37 (rats)[a] >3 (humans)[a]
Glucose 6-phosphate adduct	3 (humans)

[a]These numbers were calculated from the values in the references by methods indicated in the literature.

brain, it has been shown that as single-strand DNA damages accumulate with age, mRNA synthesis and protein synthesis decline, neuron loss occurs, tissue function is reduced, and functional impairments directly related to the central processes of aging (e.g. cognitive dysfunction and decline in homeostatic regulation) occur. Similarly, it has been shown in muscle cells that as single-strand DNA damages accumulate, mRNA and protein synthesis decline, cellular structures deteriorate, cells die, and this is accompanied by a reduction in muscle strength and speed of contraction. Thus, for brain and muscle, accumulation of DNA damage is paralleled by declines in function, suggesting a direct cause-and-effect relationship between the accumulation of DNA damage and major features of aging. In other cells, including those of liver and lymphocytes, evidence for an increase in DNA damage paralleled by a decline in gene expression and cellular function has also been observed. In general, it appears that tissues composed of nondividing or slowly dividing cells accumulate DNA damage and experience functional declines with age.

1.3 Life Span Extension by Genetic Alterations that Increase DNA Repair, Reduce Oxidative Damage, or Reduce Cell Suicide (Apoptosis) due to DNA Damage

Table 2 lists alterations in genes controlling DNA repair, oxidant status, or apoptosis that result in increased life span. The increases in life span found with the genetic alterations in Table 2 are usually an increase in the maximum life span (not just the mean life span) by about 30 to 40%. Mean life span can be extended by reductions in tumorigenesis or acute and sporadic diseases, not generally regarded as a cause of aging. The organisms with increased maximum life span reported here showed longer spans of normal vigorous activity (not merely slowed metabolism, which can also extend life span). The cellular roles

Tab. 2 Life span extension: increased life span from alterations in genes controlling DNA repair, apoptosis, or oxidant status.

Organism	*Genetic alteration*	*Pathway*	*Aging phenotype*	*Fertility phenotype*	*Spontaneous cancer phenotype*	*Cellular ROS*	*Effect on*		
							Induced DNA damage	*Spont. mutation*	*Induced apoptosis*
Mouse	100-fold excess copies MGMT gene	O^6-meG DNA repair	Life span extension	n.t.	Reduced	n.t.	Reduced O^6-meG	No effect at *H-ras* locus	n.t.
Fruit fly	Excess SOD in neurons or all tissues or with catalase in all tissues	Removes ROS	Life span extension	No change	n.t.	Reduced occurrence of oxidized proteins	n.t.	n.t.	n.t.
Fruit fly	MsrA excess	Methionine sulfoxide reductase	Life span extension	Extended	n.t.	Repaired protein oxidation	n.t.	n.t.	n.t.
Mouse	$p66^{shc}$ defect	Blocks oxidant and apoptosis parts of p53 pathways	Life span extension	n.t.	n.t.	Reduced	Reduced oxidative damage	n.t.	Reduced
Human	Higher specific activity of PARP	BER	Life span extension	n.t.	n.t.	n.t.	n.t.	n.t.	n.t.

Notes: ROS: reactive oxygen species; Spont.: spontaneous; MGMT: O^6-methylguanine-DNA methyltransferase; n.t.: not tested; SOD: superoxide dismutase.

of these genetic alterations are described below.

1. *MGMT*. One frequent type of DNA damage (see Table 1) is O^6-methylguanine, caused by low levels of alkylating agents present in food, water, air, and tobacco smoke, and formed by normal processes in the body mediated by gastric bacteria and macrophages. O^6-methylguanine is specifically repaired by a DNA repair enzyme called *O^6-methylguanine-DNA methyltransferase* (MGMT). MGMT transfers the extra methyl group from guanine in DNA to a particular amino acid within itself and becomes ''used up'' after the transfer occurs. The *MGMT* gene codes for one of the five DNA repair mechanisms listed in Section 1.1. As indicated in Table 2, when 100 copies of the *MGMT* gene were inserted into the mouse genome, these mice (under the usual conditions of mouse maintenance) had their life span extended and died at a considerably slower rate than wild-type mice.

2. *SOD*. Another important type of metabolically caused DNA damage is oxidative damage, the most frequent damage identified (Table 1). An apparently unavoidable by-product of normal respiratory metabolism is the production of reactive oxygen species (ROS) from molecular oxygen, and ROS cause oxidative damage. ROS include free radicals (where the symbol $^\bullet$ indicates an unpaired electron): the superoxide radical ($O_2^{\bullet -}$) and the hydroxyl radical ($OH^\bullet$). Another oxygen respiration by-product is hydrogen peroxide (H_2O_2). H_2O_2, if not removed, it diffuses fairly easily through the cell, and when it encounters Fe^{2+} (the ferrous ion), it can undergo the Fenton reaction and produce $OH^\bullet$ and other ROS. ROS produce a number of lesions in DNA, including base lesions, sugar lesions (the deoxyribose sugar is in the backbone of DNA), DNA–protein cross-links, single-strand breaks, double-strand breaks, and abasic sites.

The major ROS produced by the cell is $O_2^{\bullet -}$, formed in the mitochondria (the energy-producing organelles of the cell). Superoxide dismutase (SOD) occurs in two forms, manganese SOD (MnSOD) and copper/zinc SOD (Cu/ZnSOD). Both forms of SOD convert $O_2^{\bullet -}$ to the less damaging H_2O_2, and then another enzyme, catalase, converts H_2O_2 to molecular oxygen and water. MnSOD occurs in the mitochondria and Cu/ZnSOD occurs in the cytoplasm. As shown in Table 2, a number of investigators have found that inserting genes producing higher than normal levels of superoxide dismutase into the fruit fly (*Drosophila melanogaster*) genome results in life span extension. Insertion of genes producing either MnSOD or Cu/ZnSOD caused life span extension, although the artificially inserted Cu/ZnSOD only produced life span extension when its expression was restricted to the motor neurons, or solely to the adult phase of the fruit fly life cycle.

Aging has been found to correlate with increased levels of oxidative products, such as protein carbonyls and 8-oxo-guanine in DNA, and fruit flies lacking either catalase or Cu/ZnSOD have a reduced life span. Further, selection of a population of fruit flies for increased life span correlates with strongly increased expression of both MnSOD and Cu/ZnSOD. Reverse selection of these long life span flies to a shorter life span resulted in reduced expression of Cu/ZnSOD.

3. *MsrA*. In addition to DNA damage, free radicals damage proteins, lipids, and carbohydrates. Most proteins have a short half-life (averaging about three days in mouse liver). Oxidatively damaged proteins and lipids are subject to both

degradation and some repair reactions. If cellular genes that code for enzymes involved in the replacement of damaged proteins are themselves damaged, then damaged proteins may not turn over as rapidly, and protein damages may become important as they accumulate with age. Table 2 shows that insertion of an extra gene encoding bovine methionine sulfoxide reductase (MsrA) in the fruit fly genome, which helps repair oxidatively damaged proteins, leads to life span extension. Consistent with this, MsrA, when defective in the mouse, results in early aging (Table 3).

4. *p66Shc*. The *p53* gene has a central role in response to DNA damage. The p53 protein is directly active in three forms of DNA repair (NER, BER, and HRR). When there is no externally induced DNA damage, p53 has a half-life of only 5 to 40 minutes since specific enzymes target p53 for degradation. Thus, p53 is kept at a low level when there is no DNA damage. However, upon exposure of a cell to DNA-damaging agents, p53 becomes metabolically stable and, in addition, more copies of it are produced in the cell. In the presence of various types of DNA damage, p53 undergoes modifications at some of the 18 different sites within the protein. Some of these modifications [phosphorylations, acetylations, poly(ADP-ribosyl)ations, or sumoylations (covalent attachments of small ubiquitin-like proteins) allow the p53 protein to act as a regulatory agent, activating numerous other genes, carrying out different responses to different kinds or levels of DNA damage. The p53 protein can regulate or act in at least four major types of responses to DNA damage (acting as a ''master switch''), and which action or transactivation (regulating the induction of other genes) it performs depends on the level and type of DNA damage. p53 can (1) send the cell into cell cycle arrest (to allow extra time for repair of DNA damage); (2) act directly in DNA repair (see Fig. 1 for where p53 acts in NER); (3) cause the cell to switch into a cell suicide mode (apoptosis); or (4) cause the cell to produce higher levels of ROS (apparently as a preliminary to entering the cell suicide mode of apoptosis). When acting to increase the internal level of ROS and entry into apoptosis, p53 acts through another gene it controls, *p66Shc*.

When a mouse embryo is produced with both copies of its *p66Shc* gene inactive (a p66Shc ''knockout''), mouse embryo fibroblast cells derived from it have intracellular levels of ROS reduced by about 40%. Consistent with this reduction in ROS, there is also greatly reduced oxidative damage accumulation in both nuclear and mitochondrial DNA of these cells. A similar reduction in nuclear and mitochondrial DNA damage is seen *in vivo* in the tissues of lung, spleen, liver, and skin in 3- and 24-month-old *p66Shc* knockout mice, although there is no reduction in the brain, where *p66Shc* is not normally expressed. Cells of these mice are inhibited from undergoing apoptosis after cellular oxidative damage (when challenged with externally applied H_2O_2). Knockout mice without *p66Shc* show life span extension without any notable increase in cancer or other pathological defects (Table 2). Mice with a type of overactive p53 (an increase in some p53 functions) and intact *p66Shc* show early aging (Table 3). On the other hand, removal of all p53 functions (some of which are protective in DNA repair) also results in early aging (Table 3).

5. *PARP*. DNA damages caused by alkylating agents (such as those that methylate guanine, discussed above),

Tab. 3 Early aging: decreased life span from alterations in genes controlling DNA repair or protein oxidation.

Organism	*Genetic alteration*	*Pathway*	*Aging phenotype*	*Fertility*	*Spontaneous cancer*	*Effect on*			
						Cellular ROS	*Induced DNA damage*	*Spont. mutation*	*Induced apoptosis*

ionizing radiation (which produces DNA single- and double-strand breaks and oxidative damages), and ROS result in rapid activation of an enzyme called *poly(ADP-ribose) polymerase*, or PARP. PARP, similar to p53 discussed above, has a role as a ''master switch''. PARP can (1) act directly in one form of DNA repair, BER, (2) control the function of many other proteins by catalyzing the addition of ADP-ribose branched polymers onto them (either activating or repressing their function), and (3) trigger apoptosis (cell suicide). In addition, PARP controls new transcription or activities of a number of genes affecting survival or apoptosis, including p53. It was found that centenarians (humans who have lived for more than 100 years) have a modified form of PARP, which is more efficiently activated than the PARP of noncentenarians (Table 2), thereby apparently causing life span extension. In addition, the maximal poly(ADP-ribosyl)ation capacity (efficiency of activation of PARP) in leukocytes of 13 mammalian species of different life span was measured. There was a strong correlation of PARP efficiency of activation with species-specific life span.

1.4 Premature Aging Associated with Defects in DNA Repair or Increased Oxidant Status

DNA damages are so frequent (Table 1) that total absence of DNA repair of a common damage is likely to be incompatible with life. If a DNA repair pathway lacks an essential enzyme, but the missing enzyme can be, at least, partially compensated for by a similar enzyme, then repair may be adequate to allow sufficient survival and growth to show premature aging. This will also occur if a particular DNA damage is preferentially repaired by one pathway, but another repair pathway, with less efficiency, also repairs that damage.

1. *Helicase*. There are at least 31 human enzymes that are helicases or contain helicase-motif domains. Helicases are enzymes that unwind and separate the strands of DNA, usually using the hydrolysis of ATP to provide the necessary energy. Some enzymes with multiple helicase-motif domains only act as ATPases, providing energy to DNA-related processes. Helicases or enzymes with helicase-motif domains participate in DNA repair, DNA replication, and DNA recombination. Usually, the helicase activity is specific for a particular DNA configuration. Some helicases involved in particular DNA-repair pathways may be partially replaceable, at least at a low level, by other helicases. That may be why five genes, which code for enzymes with helicase functions, or helicase motifs plus an ATPase function, and which are required in different DNA repair pathways, when genetically defective, cause syndromes characterized by early aging in humans (Table 3). These syndromes are Werner syndrome, Bloom syndrome, Rothmund–Thomson syndrome, Trichothiodystrophy and Cockayne syndrome (Table 3). Similarly, in the mouse, a defect in the *Ku-80* gene, which normally activates the Ku-70 helicase function, results in an early aging phenotype (Table 3). The different helicases listed in Table 3 have specificities for HRR, NHEJ, NER, TCR or BER, so that defects in each of these DNA repair pathways may allow accumulation of different types of DNA damage, each type being able to contribute to premature aging.

2. *Topoisomerase*. Topoisomerases interact with helicases in DNA repair, recombination, and replication. When a helicase

unwinds the two DNA strands of the double helix, this introduces supercoiling of the associated DNA. Topoisomerases introduce controlled breaks plus reattachments in DNA to relieve supercoiling. There are a number of topoisomerases in mouse and human cells. The different topoisomerases interact specifically with different helicases. However, some topoisomerases may be partially replaceable by another topoisomerase at a low level. In the mouse, a mutant lacking topoisomerase IIIβ develops to maturity but shows early aging (Table 3). Topoisomerase IIIβ interacts with human RecQ5β helicase and is thought to act in DNA repair, replication, or recombination (Table 3).

3. *ERCC1*. Excision Repair Cross Complementing 1 (*ERCC1*), when defective, is another gene whose absence or truncation causes an early aging phenotype in the mouse (Table 3). ERCC1 functions in both NER and interstrand cross-link repair (in a step prior to HRR). ERCC1 has homology with an endonuclease active in NER in yeast, and that yeast endonuclease can compensate for the loss of a topoisomerase or a helicase. Thus, ERCC1 may have some functional similarity to topoisomerase or helicase in DNA repair. Conversely, loss of ERCC1 may be partially compensated for by a helicase or topoisomerase, or by another endonuclease in mouse, so that a defect in ERCC1 is not lethal but causes early aging. ERCC1 primarily functions in NER as an endonuclease as illustrated in Fig. 1.

4. *p53*. Similar to helicase and topoisomerase, p53 occurs as one of a family of enzymes, p53, p63, and p73 (and both p73 and p63 have multiple isoforms), which share significant homology and have similar functions. In particular, p73 has a role in activating DNA repair enzymes and in carrying out apoptosis in the face of excess DNA damage (see below in Fig. 3). Thus, loss of p53 may, in part, be compensated for by functions of p73 and/or p63. In Section 1.3.4, we briefly discussed an overactive form of p53 that causes early aging. This mutant form of p53 has its effect in the presence of a wild-type p53 (a heterozygous situation) where it may increase some functions detrimental to the cell. Although it is not known which functions it increases, an increase of p66Shc under p53 control could reasonably be expected to cause early aging, since it would increase DNA damage through increases in ROS. In addition, a p53 knockout mouse, lacking all functions of p53, including its functionality in three DNA repair pathways (NER, BER, and HRR), is also viable but ages prematurely (Table 3).

5. *MsrA*. As discussed in Section 1.3.3, if cellular genes, which code for activity in the replacement of damaged proteins, are themselves damaged, then damaged proteins may not turn over as rapidly, and protein damages may become important as they accumulate with age. Added activity of MsrA in the fruit fly gave greater longevity. Defective MsrA in the mouse caused early aging (Table 3).

1.5 Normal Aging in spite of Certain Defects in DNA Repair or Increases in Antioxidant Enzyme Production

If a DNA repair pathway lacks an enzyme, but the missing enzyme is partially compensated for by a similar enzyme, then repair may be sufficient to allow survival, growth, and normal aging. While such fairly good compensation may allow normal aging, the repair of DNA damages would still be less than if the repair pathway were intact, and that could lead to

increased carcinogenesis. Such fairly good compensation for DNA repair enzyme defects may be the basis for normal aging, but increased carcinogenesis, shown by mice with the DNA repair mutations listed in Table 4. As shown in Fig. 1, XPA and XPC proteins each occur as one member of a pair of complexed proteins whose function is recognition of DNA damage to be repaired by an NER pathway. It is possible that the other complexes that can recognize DNA damage can compensate, at some level, when one of the recognition complexes is absent.

Further, in some instances, genetic alterations caused increased SOD production in fruit flies but did not affect aging. However, the inserted *SOD* gene may have been turned on under the control of promoters expressing in tissues where it may not have been useful, or at rather low levels.

1.6 Negative Correlation between Mitochondrial ROS Production and Life Span

If DNA damage is the major cause of aging, ROS are a major source of DNA damage, and mitochondria are a major source of ROS, then animals with mitochondria producing higher levels of ROS may have a shorter life span, other factors being equal. Comparisons were made between long-lived birds and short-lived mammals. Pigeons, with a maximum life span of 35 years were compared with rats (of similar body size) with a maximum life span of 4 years, and parakeets and canaries (maximum life spans of 21 and 24 years, respectively) were compared with mice (maximum life span of 3.5 years). Mitochondrial ROS production was lower in the longer-lived avian species. However, in addition, pigeons were shown to have higher levels of SOD in brain, heart, and kidney than the levels shown by rats, so there was also higher antioxidant enzymatic protection in the longer-lived pigeon. This indicates that antioxidant enzymes, which confer resistance to an externally added source of ROS may be of comparable importance to longevity as endogenous rates of ROS production. The values of one measured DNA-damaged base, 8-oxodeoxyguanine, were lower in canary brain and parakeet heart nuclear DNA than in the comparison tissues of the mouse, while in the other comparisons, the level of this one damaged base was not significantly different in nuclear DNA. In another experiment quoted by Herrero and Barja, other workers showed that nuclei of starlings (another long-lived bird, maximum life span of 20 years) have less DNA breaks and abasic sites after exposure to H_2O_2 than those of mice.

Mice heterozygous for a MnSOD defect ($MnSOD^{+/-}$ mice) have higher levels of oxidative damage to DNA, protein, and lipids in their mitochondria, but no increased damage to nuclear DNA or cytoplasmic proteins. The $MnSOD^{+/-}$ mice live as long as wild-type mice, showing that mitochondrial DNA damage (as distinct from nuclear DNA damage) may not be central to longevity. This may be because there are on the order of 1,000 mitochondria per cell, and mitochondria with excess damage may be replaced by replication of less damaged mitochondria.

In Section 1.3.2, we mentioned that the long-lived strains of fruit flies have higher levels of antioxidant defense enzymes. The long-lived flies also had mitochondria that had lower levels of ROS leakage. These less leaky mitochondria, when transferred to short-lived flies through maternal inheritance (only maternal mitochondria are passed on to and maintained in progeny

Tab. 4 Normal aging: alterations in genes controlling DNA repair or oxidant status but which do not alter life span.

Organism	*Genetic alteration*	*Pathway*	*Aging phenotype*	*Fertility*	*Spontaneous cancer*	*Effect On*			
						Cellular ROS	*Induced DNA damage*	*Spont. mutation*	*Induced apoptosis*
Mouse	XPA defect	NER	Unchanged[a]	Unchanged	Increased liver cancer	n.t.	n.t.	Increased in liver, no change in brain	n.t.
Mouse	XPC defect	GGR (NER)	Unchanged[a]	Unchanged	Unchanged (when not exposed to UV light)	n.t.	n.t.	Increased	n.t.
Fruit fly	Excess SOD	Removes ROS	Unchanged	Unchanged	n.t.	n.t.	n.t.	n.t.	n.t.

Notes: ROS: reactive oxygen species; Spont.: spontaneous; n.t.: not tested.
[a]Based on observations during the first half of life span.

flies), also transferred the ability to live about 25% longer.

1.7 Other Work Indicating the Central Role of DNA Damage and DNA Repair in Aging

Numerous studies have been performed in mammals on the correlation between the ability of cells to repair DNA and the life span of the species from which the cells were taken. The life spans of the species varied from 1.5 years for the shrew to 95 years for man. Almost all of the studies showed a positive correlation between DNA repair capacity and life span. Many experiments have been performed on the effect of adding antioxidants to the diets of organisms upon the organism's life span. Although the results of such experiments are not entirely consistent, certain antioxidants have been found to generally increase life span. Vitamin E, for example, has been found to increase the life span of rat, insects, rotifers, nematodes, and paramecium.

More than 50 studies have been performed to examine the possible experimental acceleration of aging by externally applied DNA-damaging agents. Overall, it has been found that sublethal doses of ionizing radiation or DNA-damaging chemicals in the diet shorten life span, but many specific aspects of normal aging are not accelerated. Several authors have noted that the distribution (over time and in different tissues) of DNA damages induced by external agents does not closely mimic that of natural damages. This difference could explain why the life-shortening effects induced by external agents do not closely conform to natural aging. In particular, natural damages probably accumulate gradually, so they would tend to build up in nondividing cells, while they would be diluted out in dividing cells. Exposure to an external agent over a brief period, on the other hand, could cause equally large numbers of damages to nondividing and rapidly dividing cells. The effect on rapidly dividing cells could be very large by interfering with DNA replication. In addition, if oxidative damages are important in normal aging, then brain cells, which have a high level of oxidative metabolism should have more damages than most other cell types. Externally applied damages would not be expected to produce this particular type of bias. Thus, the general finding that sublethal exposure to DNA-damaging agents shortens life span, while not uniformly accelerating the natural aging process, is consistent with the DNA damage theory of aging.

1.8 Calorie Restriction and Aging

Numerous studies have shown that calorie restriction in yeast, nematode worms, fruit flies, and rodents can give life span extension. The transcription of a large number of genes is altered with calorie restriction. In rat muscle, 34 of 800 genes tested were altered in their transcription under calorie restriction, with some of the largest changes being upregulation of Cu/ZnSOD and MnSOD. In fruit flies, where 14,028 genes were assessed, 2,188 showed significant up- or downregulation after calorie restriction. In particular, DNA repair genes were downregulated (which may reflect reduced DNA damage). Evaluation of upregulated genes was problematic, however, because expression measures are proportional to the total mRNA pool, and there was massive downregulation of a large number of genes related to cell growth, and

other targeted areas. Thus, genes whose absolute transcription abundance remains unchanged will appear to be upregulated.

Overall, calorie restriction results in slower accrual of oxidative damage. The steady state oxidative damage measured represents the equilibrium between oxidant generation, oxidant scavenging, repair, and protein and lipid turnover (DNA does not turn over, although it is repaired, with damaged bases and nearby bases being replaced). The consensus is that the primary reason for lower oxidative damage observed after calorie restriction is a reduction in the generation of ROS.

1.9 General Strategies for Coping with DNA Damage and Some Consequences

Different organisms, or even different tissues within the same organism, appear to use different strategies for dealing with DNA damage. The three major strategies are described below.

1. *Cell replacement strategy*. Bone marrow and hemopoietic cells of man, guinea pig, and mouse seem to maintain their population numbers by a cell-replacement strategy. For instance, mouse bone marrow cells have a turnover time of about 1 to 2 days, and there appear to be no significant differences in the erythrocyte production from marrow stem cell lines in old and young adult mice, suggesting that DNA damages do not accumulate in this cell population. However, rapidly dividing cells are vulnerable to accumulation of mutations, which arise by errors of replication. Hematopoietic stem cells accumulate mutations (not damages) as people age from birth to 96 years. The accumulation of mutations in replicating somatic cells is widely regarded as the cause of cancer.

2. *DNA repair in nondividing somatic cell populations*. The organs including brain, muscle, and liver consist, largely, of nondividing cells, and these cells carry out DNA repair as a strategy of coping with DNA damages. However, DNA repair is less than 100% efficient, and DNA damages accumulate with time. Brain, muscle, and liver are subject to some of the more conspicuous progressive declines in function characteristic of human aging. Investigations were reviewed in 1992 on the accumulation of DNA damage in mammalian muscle, brain, and liver. In that review, 4 studies on muscle, 9 on brain, and 14 on liver reported accumulation of DNA damage with age. In most of these investigations, the type of damage measured was single-strand breaks. In 1996, an increase in DNA single- and double-strand breaks in neurons of the rat cerebral cortex with age was found. Neurons in young 4-day-old rats had about 3,000 single-strand breaks, which increased to 7,400 in neurons of old rats more than 2 years of age. Double-strand breaks increased from about 156 in young rats to about 600 in old rats. It was suggested that gradual accumulation of DNA damage with age could be a primary reason for the breakdown of the metabolic machinery leading to the eventual senescence and death of the neuron. It was found in the same year that DNA adducts, a type of DNA damage, increase in rat brain with age. Some of these were identified as malondialdehyde adducts of dGMP. It was suggested that this accumulation of DNA damages may contribute to cerebral aging. A significant increase in single-strand breaks/alkali-labile sites with age in rat liver hepatocytes were reported in 1994. Thus, numerous studies

in mammals indicate that long-lived, nondividing, differentiated cells accumulate DNA damage with time. This damage may account for many of the progressive declines in functions that define aging.

3. *Cellular redundancy*. Like repair, cellular redundancy may be another strategy for coping with DNA damage in nondividing cells. The brain has an unusually high level of oxidative metabolism compared to other organs. Brain neurons are nondividing and there is evidence for DNA damage accumulation in the brain. There is a clear loss of neurons with age. Compared to young rats, old rats have about a 50% loss of neurons in many regions of their brains. Numerous studies in humans have also shown a loss of neurons with age. The brain appears to use a strategy of cellular redundancy to compensate for the loss of neurons with age. It has been estimated that the brain is twofold larger than necessary for short-term survival. Comparisons of different mammalian species indicate that the maximum life span in mammals is directly proportional to brain size. Thus, the brain appears to be protected from loss of neuronal function by cellular redundancy, and this type of redundancy may be significant in determining life span.

1.10 Potential Immortality of the Germ Line

Cells of the germ line are capable of avoiding aging. While multicellular organisms ordinarily age and die, their germ line is potentially immortal. The germ line is distinguished from other cell lines by periodic meiosis. HRR is especially promoted during meiosis, when the homologous chromosomes are closely paired along their length. Meiosis appears to be an adaptation for removing DNA damages through HRR, and the potential immortality of the germ line may be related to this special repair capability. This idea has been tested, using single-celled paramecia that can undergo either asexual or sexual reproduction. When they grow asexually, clones of *Paramecium tetraurelia* age (show reduced vigor) and then die. These paramecia have a macronucleus containing 800 to 1,500 copies of the genome that expresses cellular functions, and a micronucleus that contains the germ line DNA.

If the macronuclei of clonally young paramecia are injected into old paramecia, the old paramecia have their life span prolonged. In contrast, cytoplasmic transfer from young to old paramecia does not prolong the life span of the old paramecia. This suggests that the macronucleus, rather than the cytoplasm, determines clonal aging. Asexually growing clones of paramecia have been found to accumulate DNA damage in the macronucleus over successive generations of clonal growth. Upon sexual reproduction (conjugation) or self-fertilization (automixis), a new macronucleus develops from the micronucleus and the old macronucleus disintegrates. Both of these processes (conjugation and automixis) include meiosis, which involves pairing of homologous chromosomes and the opportunity for homologous recombinational repair (HRR) of DNA (see Section 2.3). It was found that at a few clonal generations after meiosis, the level of DNA damage in macronuclear DNA is low but then increases as the cells undergo clonal aging. Thus, accumulation of DNA damage in the macronucleus may account for clonal aging and DNA repair during meiosis (principally HRR) may account, in large part, for the potential immortality of the germ line.

2
DNA-repair Pathways and Their Relation to Aging

2.1
NER (Nucleotide Excision Repair)

NER repairs DNA with helix-distorting single-strand DNA damages, including some oxidative damages such as the cyclopurine 8,5′-(S)-cyclo-2′-deoxyadenosine. About 30 proteins are involved in NER. The key steps in the process (Fig. 1) are (1) recognition of a DNA defect; (2) recruitment of an initial repair complex; (3) preparation of the DNA for repair through the action of helicases; (4) incision of the damaged strand on each side of the damage with release of the damage in a single-strand fragment about 24 to 32 nucleotides long; (5) filling in of the gap by repair synthesis; and (6) ligation to form the final phosphodiester bond. The two subpathways of NER, TCR, and GGR, are initiated somewhat differently, but after initiation most enzymatic steps are the same.

Individuals with the inherited disease xeroderma pigmentosum (XP) are defective in NER and are sensitive to UV radiation. About 25% of such patients also have neurodegeneration attributed to neural oxidative damage. XP patients have defects in one of seven *XP genes*, *XPA* through *XPG*, with some of their roles indicated in Fig. 1. A number of specific mutations resulting in defects in XPD, a helicase, cause a milder disease than XP, called *trichothiodystrophy*, and these mutations cause early aging (Table 3). XPA or XPC, both involved in the recognition of DNA damage (Fig. 1), when defective, do not appear to affect aging (Table 4), perhaps because if either is defective, compensation can occur to some extent. However, a double-mutant mouse, defective with a trichothiodystrophy-causing XPD mutation plus an XPA mutation, ages more rapidly than a mouse with a single XPD defect.

ERCC1, an endonuclease, associates with XPF, and then this pair associates with the initial repair complex to carry out an incision on a strand carrying the DNA damage. Defects in ERCC1 cause early aging (Table 3). CSB is an enzyme with seven helicase motifs and an ATPase function. The ATPase function is required in TCR of NER. CSB interacts with the TFIIH complex [a transcription complex (transcription factor II H)] required in NER (Fig. 1), as well as with XPA, another NER protein (Fig. 1). Patients with alterations in CSB show early aging (Table 3). p53 affects the helicase step of NER and is also required for apoptosis when damage requiring NER is excessive (Fig. 1). Defects in p53 cause early aging (Table 3). Thus, at least four NER enzymes (XPD, CSB, p53, ERCC1), when defective, may allow helix-distorting DNA damages to accumulate more rapidly than normal, leading to premature aging. In addition, the p53-regulated pathway of apoptosis (Fig. 1), perhaps triggered by helix-distorting DNA damages, if defective in p66Shc, results in life span extension (Table 2).

2.2
BER (Base Excision Repair)

BER protects mammalian cells against single-base DNA damage by methylating agents, most oxidative damages, and a large number (about 9,000 per cell per day – see Table 1) of spontaneous depurinations. BER is mediated through at least two subpathways, one involving removal and replacement of a single nucleoside and the other involving a longer patch repair of 2 to 15 nucleotides. Repair

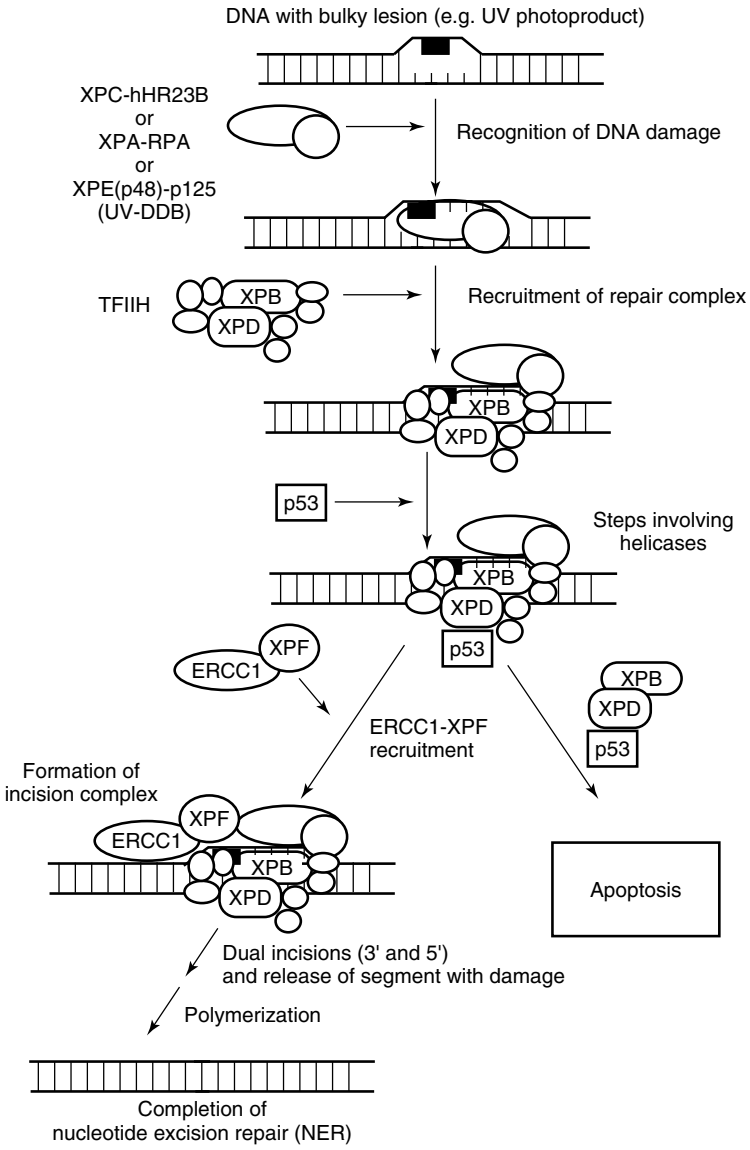

Fig. 1 Nucleotide excision repair (NER).

can be initiated by removal of a damaged base by a DNA glycosylase, which binds the altered deoxynucleoside in an extrahelical position and catalyzes cleavage of the base–sugar bond, or can occur at a site of spontaneous depurination [an apurinic (AP) site] (Fig. 2). The glycosylases that remove damaged bases are specific to the particular damage. Ref-1 (also called apurinic/apyrimidinic endonuclease or APE) then makes a 5′ nick in the DNA backbone, followed by PARP, 1 acting as a nick surveillance protein. PARP locates at the site of the single chain

nick. The nick then activates PARP, which catalyzes formation of poly(ADP-ribose) (polyAR) branched chain polymers, using the adenosine diphosphate ribose part of nicotinamide adenosine dinucleotide (NAD^+) with the release of nicotinamide (NAM) (Fig. 2). PolyAR is attached to numerous nearby proteins, including PARP itself and p53. Proteins modified by polyAR gain or lose functions. Fig. 2 indicates alteration in the transactivation role of p53 and its role in cell cycle arrest and apoptosis after it is modified by polyAR. Subsequently, a multiprotein complex (including XRCC1 and possibly DNA polymerase β and DNA ligase III) is recruited to the site by PARP, and repair patch synthesis and DNA ligation complete the process of BER (Fig. 2).

Individuals with Cockayne Syndrome show premature aging. Mutant cells with a defect in helicase motifs V or VI of Cockayne syndrome B (CSB) are defective in BER of one common oxidized base, 8-hydroxyguanine, but not defective in BER of two other oxidized bases, thymine glycol or 5-hydroxy-dCytosine. CSB is involved in the specific glycosylase step for BER of 8-hydroxyguanine (Fig. 2).

Centenarians (individuals who have lived for more than 100 years) appear to have an altered PARP with higher specific

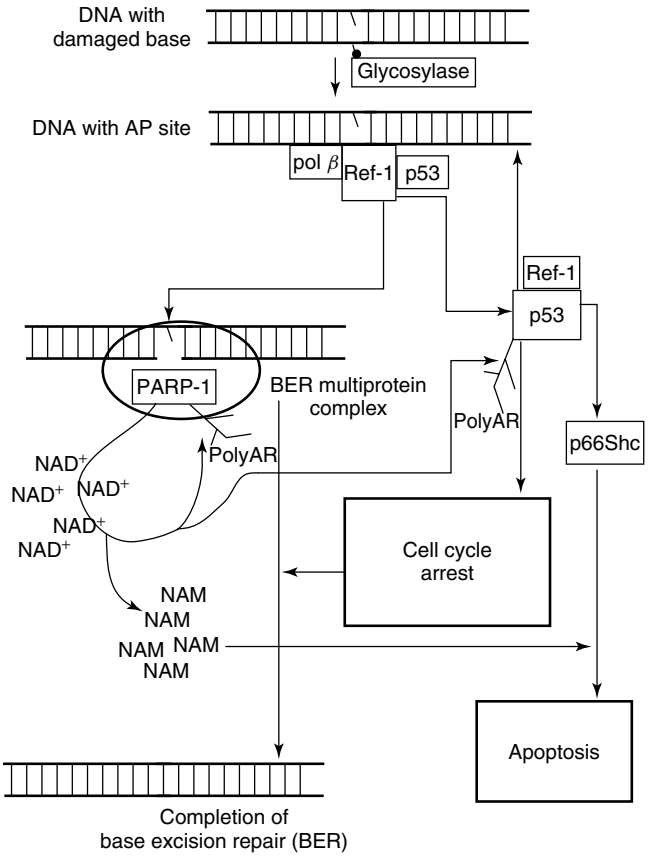

Fig. 2 Base excision repair (BER).

activity (Table 2). PARP has a central role in recruitment of the BER multiprotein complex (Fig. 2). p53 stimulates BER through interaction with ref-1 and DNA polymerase β (Fig. 2). Mice defective in p53 show early aging (Table 3).

p66Shc, when absent, causes life span extension of mice raised under protected laboratory conditions, and also longer survival of mice challenged by the oxidatively damaging compound paraquat. Mouse embryo fibroblast cells that are defective in p66Shc, when treated with H_2O_2, have much less apoptosis than wild-type cells treated with H_2O_2. This would be expected from the known role of p66Shc in the p53-controlled apoptosis pathway shown in Fig. 2. In addition, a defect in p66Shc causes reduced intracellular constitutive levels of ROS in lung, spleen, liver, and skin cells, where p66Shc is normally active. These reduced ROS levels are reflected in lower levels of oxidative DNA damage both in nuclear DNA and mitochondrial DNA of these tissues (both types of DNA damage normally repaired by BER).

Thus, two gene products involved in carrying out BER (CSB and p53), when defective, cause early aging. One gene product essential for BER, PARP, when more active, allows longer life span. One gene product, p66Shc, causes more DNA damages, needing BER when it is active. When p66Shc is absent, there are fewer DNA damages and there is life span extension.

2.3 HRR (Homologous Recombinational Repair)

Double-strand breaks, interstrand cross-links, and DNA damages blocking a replication fork can be repaired by one of two pathways, HRR or NHEJ. The selection of pathway depends on whether the cell has replicated its DNA (the S/G_2 phase of the cell cycle), so that sister chromatids are available (which favors HRR), or whether the cell is in G_0/G_1 (which favors NHEJ). The choice of HRR or NHEJ also depends on whether the cell is from embryonic tissue (which favors HRR) or from adult tissue (which, for certain damages, favors NHEJ). While HRR is especially promoted during meiosis (where there is ordinarily pairing and recombination between homologous chromosomes), HRR is also important in somatic cells. Defects in enzymes of HRR, including WRN (Werner syndrome), the RECQ3 helicase, and BLM (Bloom syndrome), the RECQ2 helicase, cause genetic instability and cancer (Table 3).

HRR is initiated through a multimeric complex, the BRCA1-associated genome surveillance complex (BASC). BASC includes the DNA repair proteins BRCA1, MSH2, MSH6, MLH1, ATM, BLM, and the RAD50-MRE11-NBS1 protein complex, some of which (BRCA1, ATM, and BLM) are indicated in Fig. 3. BASC is thought to act as a sensor for DNA damage, to which it binds. Depending on the type or amount of double-strand damage, BASC signals for (1) initiation of further steps of HRR, (2) interaction with the ''master switch p53'' to turn on cell cycle arrest (to allow more time for HRR), (3) apoptosis through the p53/p66Shc pathway, or (4) apoptosis through the p73 pathway (Fig. 3). As indicated in Fig. 3, BRCA1 and p53 have a type of feedback loop whereby BRCA1 may activate p53, and p53 may, in turn, inhibit BRCA1.

Further steps of HRR, shown in Fig. 3, involve (1) recruitment of a second homologous chromosome, (2) Rad51-dependent

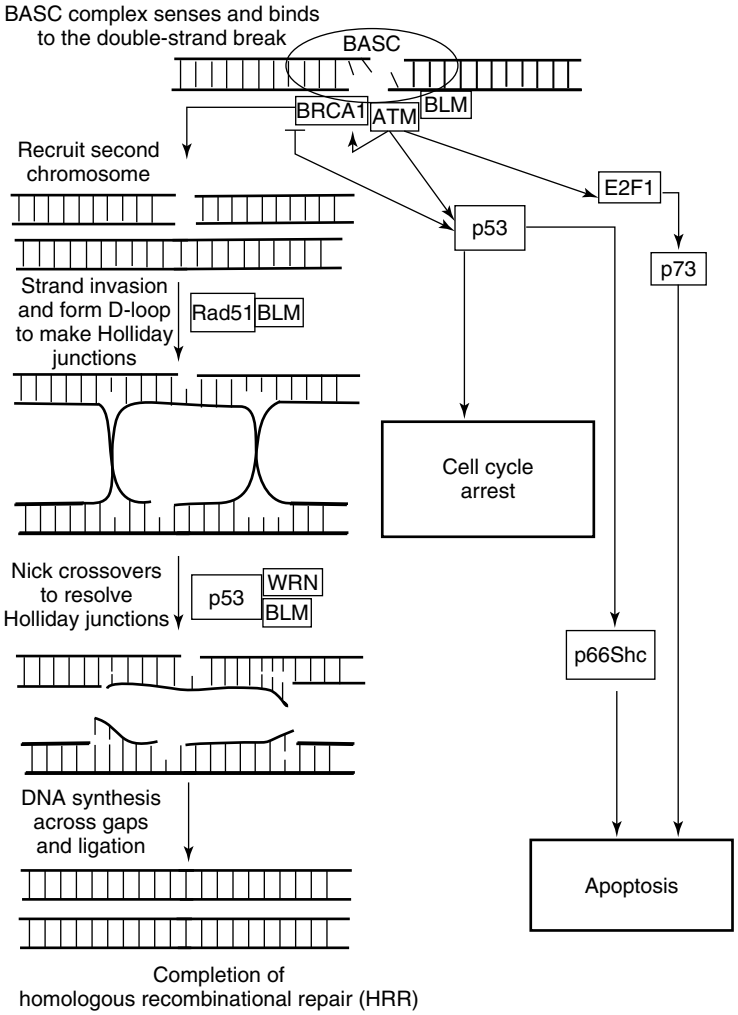

Fig. 3 Homologous recombinational repair (HRR).

strand invasion from the ends of the double-strand break plus formation of a ''D-loop'' in the invaded chromosome by strand migration facilitated by the helicase action of BLM, (3) nicking of the crossover strands to resolve the Holliday junctions, carried out by BLM and WRN helicases in association with p53 (which has a 3′ to 5′ exonuclease function and a strand transfer function that may act at this step), and (4) DNA synthesis across single-strand gaps and a final ligation step. An interstrand cross-link will be converted to a double-strand break, in part by action of ERCC1 (Table 3), and thus can also be repaired by this pathway.

Modified forms of HRR have been suggested for replicating somatic cells. In these models, the ''D-loop'' (the strand of DNA from the intact chromosome

that has been unwound and looped out to lend its information to cover the gap in the broken chromosome) is not cut to resolve the crossovers. These models, called the *synthesis-dependent strand annealing* or *migrating D-loop models*, were proposed to account for the prominence of mitotic gene conversion without reciprocal exchange observed in replicating cells. The standard model of HRR is shown in Fig. 3, however, since it applies to nonreplicating somatic cells, the major cells showing decreased function with age, and to germ line cells, as discussed below.

As indicated in Table 3, four genes that act directly in HRR (*BLM*, *WRN*, *p53*, and *ERCC1*), when defective, cause early aging. Oxidative damage to DNA includes double-strand breaks. Thus the gene product, *p66Shc*, which increases the level of intracellular ROS, may cause more DNA damage, needing HRR when it is active. When *p66Shc* is absent, there are fewer such DNA damages and there is life span extension.

2.4 NHEJ (Nonhomologous End Joining)

As noted in Section 2.3, double-strand breaks, interstrand cross-links, and DNA damages blocking a replication fork can be repaired by one of two pathways, HRR or NHEJ. HRR is an accurate repair pathway, obtaining information missing within a damaged chromosome from a homologous, undamaged chromosome. NHEJ, alone, however, is inaccurate at the nucleotide level because it involves end-joining reactions between single-stranded ends to form junctions containing regions of microhomology of 1 to 10 base pairs within 20 base pairs of the ends. However, coupled homologous and nonhomologous repair can occur (using short homologous regions on a nearby heterologous chromosome) to employ NHEJ in a more accurate process, with short regions of gene conversion from the undamaged chromosome. In addition, it was recently shown that NHEJ, when the number of double-strand breaks is small, serves to properly reconnect the two broken ends of a given chromosome. In the absence of NHEJ, more misrejoined chromosomes (chromosomal aberrations) are produced.

NHEJ of a double-strand break is illustrated in Fig. 4. Two Ku heterodimers (Ku consists of Ku70 complexed with Ku86) attach to two broken ends of a chromosome. Ku then recruits DNA-PK_{cs}, which becomes activated by the interaction with Ku and a DNA end. Activated DNA-PK_{cs} phosphorylates a wide range of DNA binding proteins and also phosphorylates Werner syndrome protein (WRN). WRN displaces DNA-PK_{cs} and, through interaction with Ku, activates its WRN exonuclease function, trimming back single strands on the chromosome ends. The complex of Mre11, Rad50, and NBS1 (MRN), plus BRCA1, may interact at this point with Ku to keep the end joining fairly accurate. In the absence of WRN, frequent gross chromosomal rearrangements occur. The Bloom syndrome protein, BLM, is also needed to keep the NHEJ fairly accurate. BLM may also assist with the alignment of two nearby ends for fairly accurate NHEJ (BLM is drawn with a dashed oval in Fig. 4 to indicate that its role in the NHEJ repair process is not yet clearly established). Pol μ then associates with small gaps in the aligned and stabilized joined ends, and pol μ, in association with Ku, recruits ligase IV and XRCC4 (X-ray repair cross complementing protein 4). Pol μ fills in

the gaps and ligase IV and XRCC4 complete the NHEJ repair of the double-strand break in a chromosome.

As indicated in Table 3, three genes that act directly in NHEJ [*Ku80* (also called *Ku86*), *WRN* and *BLM*], when defective, cause early aging. *Ku80* is only active in NHEJ, while *WRN* and *BLM* also have roles in HRR.

2.5 MGMT (O^6-Methylguanine-DNA Methyltransferase)

As indicated in Table 1, O^6-methylguanine is a frequent DNA damage. O^6-methylguanine is specifically repaired by a DNA repair enzyme called *O^6-methylguanine-DNA methyltransferase* (MGMT). As

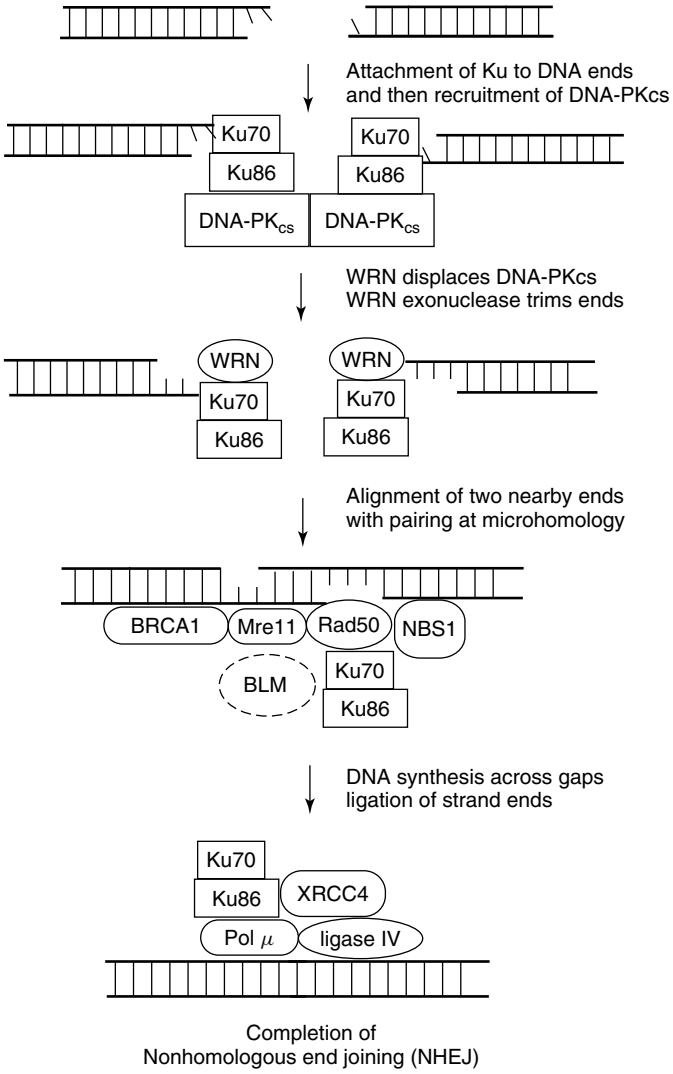

Fig. 4 Nonhomologous end joining (NHEJ).

indicated in Table 2, excess MGMT results in decreased aging (life span extension).

2.6 Enzymes of DNA Repair Pathways and Enzymes Regulating DNA Damage–inducing ROS Contribute to Determination of Aging

Eleven specific DNA repair enzymes distributed among NER, BER, HRR, NHEJ and MGMT were found to increase lifespan when elevated or decrease life span when defective (Tables 2 and 3). In addition, alterations of four enzymes causing reduced levels of DNA-damaging ROS (increases of Cu/ZnSOD, MnSOD or catalase, or loss of p66Shc) also increase life span. These findings strongly support the DNA damage theory of aging.

3 The DNA Repair (and Complementation) Theory of Sex

3.1 Meiosis, an Adaptation for Repairing Germ Line DNA

It is useful for further discussion to define sexual reproduction and to clarify its key components. Such a definition, to be general, should encompass sexual processes in all organisms, both eukaryotes and prokaryotes. *Sexual reproduction is the process by which genetic material (usually DNA) from two separate parents is brought together in a common cytoplasm where recombination of the genetic material ordinarily occurs, followed by the passage of the recombined genome(s) to progeny.* Thus, sexual reproduction has two basic elements: (1) recombination, in the sense of the exchange of genetic material between two homologous chromosomes, and (2) outcrossing, in the sense that the homologous chromosomes from two different individuals come together in the same cell.

In eukaryotes, the germ line is the cellular lineage that connects successive meioses. The germ line is a key feature of sexual reproduction. In obligate sexual organisms such as humans, the germ line is potentially immortal (see Section 1.9) in contrast with the somatic line. This feature of the germ line presumably is due to adaptations present in the germ line that are lacking in the somatic line. Meiosis is a process unique to the germ line, and it appears to be an adaptation specifically for promoting recombinational repair (HRR), since a major characteristic of meiosis is the close pairing of homologous chromosomes.

Some diploid organisms form gametes (such as sperm and egg cells) by meiosis, but then undergo self-fertilization or automixis (a process in which two haploid products of meiosis fuse to form a diploid zygote). Such processes are common in plants and invertebrates. Self-fertilization and automixis are not strictly sexual processes since they lack the outcrossing feature of sex. However, many of the organisms that undergo these asexual processes are also facultatively sexual. In the following discussion, we assume that meiosis serves essentially the same function in all organisms in which it occurs and that the germ line in facultative or obligate self-fertilizing and automictic eukaryotes is the cell lineage that connects successive meioses.

Tab. 5 Modes of reproduction among higher plant species.

Reproduction strategies	*Number*	*Percent*
Principally cross-fertilized	830	55
Self-incompatible, dichogamous, or dioecious		
Dichogamy: male and female parts mature at different times;		
Dioecious: unisexual (male or female) flowers on different plants		
Partially self-fertilized, partially cross-fertilized	105	7
Principally self-fertilized (autogamous)	229	15
Facultative apomicts (can be cross-fertilized)	16	1
Apomixis: vegetative methods of reproduction including propagation by runners or bulbs and agamospermy		
Agamospermy: embryos and seeds formed by asexual means		
Facultative apomicts, can be self- or cross-fertilized	3	0.2

Apomicts, not known if also self- or cross-fertilized	199	13
Obligate apomicts	121	8

3.2 Frequency of Sexual Reproduction

Sexual reproduction is a widespread strategy for reproduction. About 99.9% of the approximately one million known animal species are sexual. Among higher plants, the majority of species are sexual. As shown in Table 5, only 8% of higher plants are known to be obligate apomicts that reproduce only by vegetative means such as by runners, bulbs, or by asexual formation of seeds. Sex is also common among the simple eukaryotes, including fungi, algae, and protozoa. Sex is found among bacterial species as well, and is common in bacterial viruses and animal viruses.

3.3 Costs of Sex

Sex, while widespread, is very costly to the organism using it. For example, a sexual female lizard passes only 50% of her genes to a particular egg, while a comparable nonsexual (parthenogenetic) female lizard passes 100% of her genes to each egg. Thus, a sexual female is only half as efficient in propagating her genes as a nonsexual female (all other factors being equal). In addition, when two individuals must find each other to mate, there is a cost of searching out the other party.

Another cost of sex arises from the randomization of genetic information during meiosis. A parent organism, which has met the test of survival, has by definition, a well-adapted combination of genes. The process of meiosis, which includes recombination, generates untested new combinations of genes to be passed on to progeny. These new combinations, on average, should be less successful than the parental combinations of genes because random changes in successful genetic information are more likely to be deleterious than beneficial.

The noted biologist E.O. Wilson describes sex in humans as a ''gratuitously consuming and risky activity''. Reproductive organs are anatomically

complex in humans and these are vulnerable to such problems as ectopic pregnancy and venereal diseases. Further, courtship activities are costly. Even at the microscopic level in humans, genetic processes for determining sexual development are easily perturbed with one sex chromosome too few or too many, or a shift in the hormone balance of a fetus, causing abnormalities in physiology and behavior.

Clearly sex has large costs.

3.4 Benefits of Sex

Sex must have a large benefit to make up for its large costs. A major function of sex is to counteract two types of ''noise'' in the transmission of genetic information from parent to progeny: DNA damage and mutation.

As pointed out in Section 1.1, about 95,000 DNA damages occur, on average, per day per cell in the rat. Most of these are single-strand damages that can be removed by excision repair or other repair processes that only need the redundant information present on the opposite strand of DNA. However, excision repair of single-strand damages is not 100% efficient, and double-strand damages also occur at significant frequencies (Table 1). Such DNA damages remaining in germ cells (e.g. egg and sperm, in mammals) would cause the death of zygotes and loss of potential progeny. During the meiotic stage of the sexual process, however, HRR is strongly enhanced by the systematic homologous pairing of chromosomes, the major feature of meiosis. This enhanced HRR repair is one major benefit that can compensate for the costs of sex, since clearing the germ line of lingering damages can greatly increase viability of progeny.

The other type of noise in the transmission of genetic information from parent to progeny is mutation. Mutation is quite different from DNA damage. A mutation is a change in the DNA sequence rather than a change to a deformed DNA structure (DNA damage). Mutation and DNA damage have distinctly different consequences. Mutations can be replicated (when DNA replicates) and thus can be inherited, while a damage cannot be replicated. However, damages can be recognized by enzymes and repaired, whereas mutation cannot be recognized and thus cannot be repaired.

Genes carrying mutations often code for nonfunctional proteins. If one of a pair of chromosomes in a diploid cell carries a mutation in a given gene, and the second chromosome carries the homologous gene in a functional form, this second gene can usually provide an adequate level of gene expression for the organism to function normally. This masking of the expression of mutant genes by wild-type genes is called *complementation*. Complementation is available in the diploid phase of the life cycle of organisms. However, complementation is most beneficial when an organism undergoes outcrossing.

To see why mutation makes it beneficial to have outcrossing, consider a hypothetical population of diploid organisms that is strictly inbreeding (all of the organisms are self-fertilizing) and assume that the population has been long established. In such a population, the rate at which new mutations arise will be balanced by the rate at which they are lost from the population by natural selection. In this self-fertilizing population, each mutation present in an individual will have a one in four chance of being paired with

the same mutation (becoming homozygous recessive) in each progeny. If an average of one to several deleterious mutations are present in each individual, the cost of inbreeding in terms of defective progeny would be high. If a hypothetical outcrossing individual should arise in such an otherwise inbreeding population, any mutations in this outcrosser would very likely be complemented by the wild-type alleles from its mating partner and thus defective progeny would be avoided. Complementation would occur because the homologous chromosomes from the two parents are not likely to carry the same mutations. Thus, loss of progeny due to expression of mutations would be greatly reduced. This gives a strong immediate selective advantage to switching to outcrossing from inbreeding.

This advantage would not last indefinitely in our hypothetical example. Because of the ability of outcrossers to mask deleterious mutations by complementation, mutations would not be weeded out by natural selection as efficiently as in inbreeding individuals. Eventually, the mutations that build up in the population will cause as much lethality to progeny of the outcrosser as that in the original inbreeding population. However, if the outcrosser tried to switch back to inbreeding, there would be a great loss of progeny due to the larger number of mutations now present. In summary, there is a large immediate benefit in switching from inbreeding to outcrossing and a large immediate disadvantage in switching back. Therefore, mutation provides a selective pressure to maintain the outcrossing feature of sexual reproduction among diploids.

Overall, meiosis, with its promotion of recombinational repair, may be the only way to efficiently correct endogenous double-strand damages and leftover single-strand damages in the diploid cells that produce germ cells. On this view, the recombination aspect of sex is an adaptation for dealing with DNA damage, a major type of genetic noise. Furthermore, outcrossing allows the masking of mutations through complementation. The outcrossing aspect of sex deals with mutation, the second major type of genetic noise.

3.5 Repair of DNA Damage of the Germ Line in Nonmeiotic Cell Divisions

The germ line is characterized by periodic events of meiosis, but during the intervals between such events, cell divisions are ordinarily by mitosis. Cells of the germ line are presumably capable of the same types of repair processes that occur in somatic cells, discussed in Section 2. For instance, there is a relatively high level of PARP activity in premeiotic and meiotic spermatocytes, an indication of BER. Fraga and coworkers in 1990 measured the accumulation of one type of oxidatively damaged DNA base, 8-hydroxy-2′-deoxyguanosine, in various tissues of the rat. Although the average accumulation in the rat kidney was 80 residues per cell per day, there was no detectable accumulation in the testes. This lack of accumulation in the testes of normal individuals can be interpreted as a reflection of efficient BER in the germ line of normal individuals.

It is notable, in Table 2, that where life span is extended, fertility is either normal or extended as well, where it has been tested. In Table 3, where defects in DNA repair cause early aging, fertility is always reduced, where it has been tested.

3.6
Meiotic Recombination in Eukaryotes Probably Evolved from Recombination in Prokaryotes

Several workers have suggested that the processes of recombination in prokaryotes and eukaryotes share a common ancestry. Dougherty in 1955 may have been the first to conclude that the evolution of sexuality as it exists today was the result of a single phylogenetic sequence. He based this conclusion on the fact that recombination in bacteriophage and in bacteria, on the one hand, and meiotic recombination in eukaryotes, on the other hand, seemed to share fundamental similarities. Later Stahl in 1979 also concluded that despite numerous differences in detail, the "similarities in recombination in creatures as diverse as the phage and fungi are impressive."

In recent years, there has been considerable work on the biochemistry of recombination, with an emphasis on the RecA protein of the bacterium *Escherichia coli*. This protein catalyzes the key steps in recombination of homologous DNA pairing and strand exchange. Homologs of the *E. coli RecA* gene have been identified in over 60 bacterial species and in bacteriophage T4, suggesting that RecA-catalyzed recombination is very common in the prokaryotic world. Since about 1992, there has been much work indicating that RecA homologs play a key role in meiotic recombination in fungi and vertebrates. A RecA homolog in humans shows 30% amino acid sequence identity with the *E. coli* RecA protein. RecA homologs in yeast and humans form helical filaments with DNA, such as those formed by *E. coli* RecA, leading to the conclusion that the RecA protein has been conserved from bacteria to man. These findings suggest that eukaryotic meiotic recombination and recombination processes in extant bacteria are probably both derived from a common ancestor that existed before the divergence of prokaryotes and eukaryotes, at least 1.8 billion years ago.

3.7
Homologs of the Bacterial RecA Protein Have a Key Role in Eukaryotic Meiotic Recombinational Repair

Substantial evidence indicates that RecA homologs have a central role in recombinational repair during meiosis in yeast. The yeast *rad*51 and *dmc1* genes are homologs of the *recA* gene of *E. coli*. The Rad51 and Dmc1 proteins probably share redundant functions, since recombination is reduced by only a few fold in *dmc1* and *rad51* single mutants, but *dmc1* and *rad51* double mutants are profoundly defective in meiotic recombination. The Rad51 protein acts during both mitosis and meiosis, whereas Dmc1 protein acts only during meiosis. Both Rad51 and Dmc1 proteins function in repair of double-strand breaks. Sung in 1994 demonstrated that Rad51 protein, like *E. coli* RecA protein, catalyzes ATP-dependent homologous DNA pairing and strand exchange. The Dmc1 protein has an overall similarity to *E. coli* RecA protein in tertiary structure. These findings suggest that the yeast Rad51 and the bacterial RecA proteins have similar functions in recombinational repair. Morita and coworkers showed in 1993 that in the mouse a *recA* homolog is expressed at high level in the testes. Shinohara and coworkers in 1993 also showed that the mouse *recA* homolog is expressed at a high level in the testis and ovary, and suggested that the protein product of this gene is involved in meiotic recombination. The expression of a *recA* gene homolog has also been demonstrated in chicken testis and ovary and in human

testes. The human RecA homolog carries out the distinctive reactions of *E. coli* RecA protein, including DNA-dependent hydrolysis of ATP, renaturation of complementary strands, homologous pairing of a single strand with duplex DNA, and strand exchange. A pair of *recA* gene homologs of the lily, *lim15* and *rad51*, which are also homologs of the yeast *dmc1* and *rad51* genes, were found by Terasawa and coworkers in 1995. The *lim15* gene in lily is specifically expressed in meiotic prophase during microsporogenesis. Thus, in both animals and plants, homologs of bacterial *recA* appear to have an important role in meiotic recombination.

3.8 The Adaptive Function of Recombination Appears to Be Removal of DNA Damage

DNA repair is probably the principal adaptive function of the RecA protein and its homologs. RecA protein binding is largely limited to regions in the DNA containing suitable nucleation sites, especially single-strand gaps. A variety of DNA damages cause structural perturbations that provide favorable nucleation sites.

About 100 ATPs are hydrolyzed for every base pair of heteroduplex DNA generated by RecA-mediated strand exchange. In 1993, Cox reviewed evidence that the energy released by ATP hydrolysis is used specifically to allow the strand-exchange process to traverse damaged regions of DNA. He argued that this use of ATP is readily understood as an adaptation of repair of DNA damage. Thus, the evidence reviewed by Cox indicates that the adaptive function of RecA homologs, acting during meiosis, is DNA repair.

In humans, HRR is carried out by a group of interacting proteins in which the RecA homolog Rad51 has a central role. Other proteins involved in HRR in humans include the products of genes *BRCA1*, *BRCA2*, *ATM*, *ATR*, *FANCD2*, *HMLH1*, and *p53*.

These proteins appear to be responsible for HRR during meiosis and for HRR between sister DNA homologs in somatic cells. HRR is employed in removing a variety of DNA damages, particularly double-strand damages such as double-strand breaks and DNA cross-links. The proteins named just above, involved in HRR, also appear to use their DNA damage recognition capability to induce apoptosis (a form of programmed cell death) when the number of DNA damages in a cell is higher than those that can be repaired. In somatic cells, apoptosis is a protective mechanism for the whole organism since it eliminates cells that might otherwise survive despite having unrepaired DNA damages, and upon replication acquire mutations.

In fact, germ line mutations in genes *BRCA1*, *BRCA2*, *ATM*, *ATR*, *FANCD2*, *HMLH1*, and *p53* predispose individuals to cancer. Cancer predisposition results from an inadequate response to DNA damage in somatic cells leading to increased mutations, some of which cause progression to malignancy. Thus, the central function of these genes is to cope with DNA damages, either to repair the damages, or if their number in a cell is unmanageable, to induce apoptosis.

Males that are defective in *ATM* or *p53* are unable to respond appropriately to DNA damage during meiosis, and, as a likely result, they suffer from low sperm quantity and quality. The high effectiveness of DNA damage removal processes during normal meiosis is reflected in mice, where there is a one-third lower rate of mutation in germ cells compared to that in somatic cells.

Overall, the evidence reviewed in this section lends strong support to the idea that the primary general function of recombination enzymes, whether in somatic cells or during meiosis, is to remove DNA damage, either by repair or apoptosis.

3.9 Other Expectations of the DNA Repair and Complementation Theory of Sex

If DNA damage and its repair are important in maintaining sexual reproduction, then certain expectations follow. If recombination during meiosis and sexual reproduction reflect recombinational repair of germ line DNA, then there should be other evidence of avoidance of DNA damage in the germ line as well.

As indicated in Table 1, the largest known source of DNA damage is oxidative damage. Such damage occurs due to endogenous cellular metabolism. Presumably, to avoid DNA damage, germ line cells should have evolved ways to avoid high levels of metabolism. Eggs would seem, at first sight, to be poor candidates for avoiding metabolism. They are, in general, much larger than somatic cells of the organism (e.g. egg cells have about a 1,000-fold greater mass than somatic cells in humans). It requires considerable metabolism to produce large egg cells. However, much of the cytoplasmic material within an egg cell is generated by the activity of other cells. Some insects have nurse cells around each egg cell. These nurse cells are connected to the egg cell by cytoplasmic bridges and provide most of the ribosomes, mRNA, and proteins of the egg cell. The nurse cells themselves contain hundreds to thousands of copies of their genomes, presumably to protect the nurse cells themselves from losing function from the oxidative damage they may suffer while providing large amounts of metabolic products for the egg cell. Vertebrate egg cells are surrounded by follicle cells rather than nurse cells. The follicle cells do not have cytoplasmic bridges to the egg cell, but rather have small gap junctions connecting them to the egg. While these gap junctions are not large enough to transmit bulky macromolecules, they do transmit precursor molecules to the egg. In addition, for chickens, amphibians, and insects, the yolk proteins accumulated by the egg are made in liver or liver-type cells. These mechanisms allow eggs to be protected from oxidative damage while they store up material to sustain the zygote in its initial growth.

Sperm or pollen cells, in contrast to egg cells, are usually the smallest cells of an animal or plant. This allows a different strategy for effective protection against oxidative damage to their DNA. Because of their very small size, minimal metabolism would have been used in their formation. Thus, both egg and sperm production appears to have been adapted to circumvent the production of DNA damage in their especially important germ line DNA.

Another way to avoid production of sperm with damaged DNA is for spermatogenic cells with DNA damage to undergo cell cycle arrest to allow more time for meiotic repair, and then, if this fails, to undergo apoptosis. The p53 protein plays a key role in mediating cell cycle arrest in response to DNA damage. Low-level irradiation was found to activate a p53-dependent premeiotic delay, allowing time for increased DNA repair leading to increased motile spermatozoa. Higher levels of γ-irradiation induced p53-independent apoptosis during meiosis.

If complementation of mutations is important in maintaining the outcrossing

aspect of sex, this should be consistent with general biological observations as well. Indeed, both in animals and in plants, it is usually seen that when hybrids are formed from the crossing of two genetically distinct inbred lines, these hybrids are more vigorous than either of their two parental lines. This hybrid vigor is responsible for much of the crop improvement that has been achieved in modern agriculture. The opposite side of this observation is the fact that consanguineous marriages, in humans, result in an increased frequency of impaired offspring. Observations in other animals and in plants suggest that close inbreeding results in the production of less vigorous progeny. This inbreeding depression appears to be due largely to expression of deleterious recessive mutations and reflects in part the cumulative effect of numerous mildly deleterious mutations.

4
Vegetative Survival Strategies

4.1
Survival of Vegetative Cell Populations

Vegetatively growing populations of bacteria can be regarded as potentially immortal as long as nutrient resources are abundant. However, even in such populations there appears to be constant attrition due to DNA damage and deleterious mutation.

Flowering plants generally reproduce sexually, with gamete formation by a meiotic process followed by gamete fusion as the prelude to embryogenesis and seed formation. Plants, unlike most animals, are also able to generate complete new individuals of similar genetic constitution from vegetative parts. Meristematic buds or excised pieces of tissue can propagate in the appropriate environment. Apparently, plant vegetative cell lines can be maintained indefinitely under appropriate conditions. These lines probably maintain themselves by a strategy of replacement, where cells with lethal unrepaired DNA damage or expressed deleterious mutations die and are replaced by replication of nondefective cells. Nevertheless, in some plant tissues DNA damage may accumulate. For instance, in dry seeds, fragmentation of nuclear DNA occurs with time.

Most forest trees live for at least 100 years, many of them for more than 300 years, and a few survive for more than 1,000 years. Clonal tree species may occupy a location for several thousand years. Most of the tree is dead, and only a thin shell of dividing cells (cambium) occurs around the trunk and in the leaves. A tree actually represents a free-living clone of cells in which selective removal of cells with irreversible accumulated damage is constantly occurring. One would not expect to find old cells in a tree any more than one would find old cells in a growing culture of bacteria. The evidence discussed in this section suggests that some proliferating cell populations can cope with unrepaired DNA damage by a replacement strategy, which can be maintained indefinitely as long as nutrient resources are abundant and the level of unrepaired DNA damage is not excessive.

4.2
Vegetative Survival Strategy for Mitochondria (and Chloroplasts) in the Germ Line

An analog of cellular replacement at the molecular level (''molecular replacement'') facilitates the purging of both DNA damage and deleterious mutations in cytoplasmic genomes (mitochondria and

chloroplasts) of germ cell lines. While nuclear genes occur as single copies per gamete, there are thousands of mitochondrial DNA (mtDNA) molecules in most cells, and several hundred thousand may occur in a mature oocyte. The many mtDNAs in oocytes appear to stem from a vastly smaller pool of mtDNA molecules that must have survived a process of replicative segregation in earlier cytokinetic divisions of the germ line lineage, since most heterogeneity of mtDNA is distributed among, rather than within, individuals. This implies that there are mtDNA population bottlenecks in germ lines. That is, the mtDNA, which is generally solely transmitted from one generation to the next through the oocyte, is of only one or a few genotypes. Avise concluded that the mtDNA molecules that survive and replicate to populate a mature oocyte probably have been scrupulously screened by natural selection for replicative capacity and functional competence in the germ cell lineages they inhabit. This strategy, at the molecular level, is equivalent to a vegetative cell replacement strategy for cell lineages that do not have a sexual cycle. While the mitochondria and chloroplasts within cells follow a vegetative replacement strategy, they, like vegetatively replicating bacteria and yeast, utilize homologous DNA recombinational repair to remove DNA damages due to oxidation or environmental stresses.

4.3 Dolly the Cloned Lamb, Cumulina the Cloned Mouse, and Low Success of Cloned Mammals

The evidence reviewed above indicates that germ cells, having undergone meiosis, are relatively free of DNA damage, and thus should be able to give rise to viable offsprings with high probability. At lower probability, a given somatic cell nucleus may also be sufficiently free of damage to be able to produce viable progeny if transferred to an enucleated egg cell.

Eight viable lambs were derived in 1997 – one (named Dolly) from donor cells of a mature sheep, four from donor embryo-derived cells, and three from donor fetal fibroblast cells. For Dolly, the lamb derived from a somatic cell of a mature sheep, they first made 277 fused couplets (enucleated oocytes fused to donor cells), using donor cells from their 3rd to 6th passage, cultured from the mammary gland of a six-year-old pregnant ewe. A morula or blastocyst was able to form from only 11.7% of the cultured fused couplets from the mature ewe. By comparison, when couplets were derived from embryo or fetal fibroblast cells, a morula/blastocyst was formed 27 to 39% of the time. Some of the morula/blastocysts implanted in recipient ewes formed fetuses detectable by ultrasound at 50 to 60 days. Subsequently, 62% of these fetuses were lost, a much greater proportion than the estimated 6% after natural (meiosis based) mating in sheep.

Similar observations were made with mice. Ten healthy mice were cloned, the first of which was named Cumulina, from donor nuclei of differentiated, nonreplicating granulosa cells of mature mice injected into enucleated recipient mouse oocytes. Cumulina and the other nine cloned healthy newborn mice were the only successful progeny produced from 800 injected oocytes, which had formed embryos and were transplanted into foster mother recipient mice. In multiple cloning experiments by these authors, the rate of successful implantation of embryos was 57

to 71%, formation of fetuses was 5 to 16%, and full-term development was 2 to 3%.

The low survival rate to full development in both sheep and mice could have three possible explanations. First, injuries introduced by the experimental manipulation of the embryos before implantation might be deleterious to further development. Even unreconstructed embryos experience some increased prenatal loss after manipulation or culture. Second, the differentiated donor nuclei, transplanted into the recipient oocytes, have to reprogram their developmental clock to zero, and errors in this process may have deleterious effects on fetal development. Third, the low survival of fetuses may be a consequence of the greater amount of DNA damage in donor somatic cells (than in meiotically produced gametes), which can give rise to deleterious mutations when replicating after transfer to an oocyte.

The gene expression profile of about 10,000 genes in the placentas and the livers of surviving cloned mice derived by nuclear transfer were obtained in 2002. The transferred nucleus came from either an embryonic stem (ES) cell or from a mature, differentiated cumulus cell. They compared those gene expression profiles (derived from ES nucleus or cumulus cell nucleus) with the gene expression profile in the same tissues (placenta, liver) of healthy mice derived from normal mating. These comparisons showed that several hundred (at least 4%) of the expressed genes had pronounced dysregulation in the cloned mice, probably accounting for the altered phenotype of cloned individuals (many cloned mice were obese, etc.). Their evidence pointed to difficulty in reprogramming the developmental clock back to zero, in the low percentage of surviving mice.

In humans, about 50 to 80% of all natural meiosis-based conceptions fail to result in live birth. Cytogenetic studies of spontaneous and induced abortions and on perinatal deaths indicate that many types of chromosome abnormalities are present in these failed conceptions. Chromosome abnormalities often derive from DNA damages.

Thus, DNA damage may be a serious problem for germ cells despite available mechanisms for avoiding and repairing such damage, and this problem may be considerably greater in nonmeiosis-derived conceptions.

5 Three Levels of Sexual Communication Reflect (1) DNA Repair, (2) Complementation, and (3) Selection for Fitness

Sexual communication occurs when signals are used to promote or modulate sexual interaction between individuals. Sexual communication is prevalent among organisms from bacteria to man. Sexual communication occurs at three levels. Level 1: the first level of sexual communication includes signals that increase the likelihood that two organisms will come together for sexual interaction. Level 2: the second level involves signals that modulate the sexual interactions to inhibit inbreeding or facilitate outbreeding. Level 3: the third level includes signals that further modulate the sexual interactions to promote selection among potential mating partners based on relative fitness. Evidence indicates that the selective advantages of the three levels of sexual communication are, respectively, (1) the repair of DNA damage, (2) the masking of mutation, and (3) the choice of a fit mating partner.

5.1 Sexual Communication in Bacteria, Primarily for DNA Repair

The simplest organisms in which sexual communication occurs are bacteria. Bacterial transformation is a form of sexual interaction in bacteria and has been shown in several bacterial species to involve sexual communication. Transformation involves the transfer of naked DNA from one member of a bacterial population to another through the surrounding medium. Transformation occurs naturally in a wide range of bacterial species. The bacteria that take up transforming DNA ordinarily incorporate this DNA into their genomes by recombination. Transformation is an evolved, rather than an incidental, trait since it results from a complex, energy-requiring, developmental process. For a bacterium to bind, take up, and recombine exogenous DNA into its genome, it must first enter a special physiological state referred to as *competence*. Transformation involves expression of genes required for competence and for recombination. In the completely sequenced genome of *Haemophilus influenzae*, transformation is promoted by at least 15 genes of the 1007 for which role assignments can be made. In another bacterium, *Bacillus subtilis*, about 40 genes necessary for competence have been identified.

Transformation in a number of bacterial species depends on the production of an extracellular factor (referred to as *competence factor*), which, upon release into the surrounding medium, induces the competent state in neighboring cells in the population. These extracellular factors are examples of pheromones. (Pheromones are molecules released by an organism into the external medium to influence other individuals of the same species.) These extracellular factors have been studied in *B. subtilis, Streptococcus pneumoniae,* and *B. cereus*. In *B. subtilis,* two different extracellular peptide pheromones are used for competence development. In *S. pneumoniae,* the competence pheromone is a 17 amino acid peptide.

The adaptive function of bacterial transformation has been studied in *B. subtilis* as a model system for understanding the adaptive function of bacterial transformation generally. The results indicated that transformation provides external DNA template for recombinational repair of DNA damage in the recipient. Transformation and recombinational repair in *B. subtilis* require the RecE protein, which is a homolog of the well-studied RecA protein of *E. coli*. DNA damages arising from such sources as UV irradiation, endogenous oxidative free radicals, and desiccation are a pervasive problem for bacteria. The RecE protein of *B. subtilis* probably catalyzes recombinational repair of these prevalent DNA damages. Thus, sexual communication via pheromones in bacteria is probably an evolved mechanism to promote sexual interaction for recombinational repair of prevalent DNA damages. This is ''Level 1'', the primary level of sexual communication.

Transformation in bacteria involves partial diploidy as an intermediate stage. Even though the initial advantage of this process, we think, was recombinational repair of DNA damage, diploidy (or partial diploidy) may also provide the benefit of masking deleterious recessive mutations through complementation. Thus, recombinational repair in bacteria may have set the stage, or may have been a precursor to, natural selection for diploidy as a distinct phase of the sexual cycle in eukaryotes. Further, recombinational variation is produced as a by-product

of recombinational repair in bacterial transformation as well as in other sexual processes. The infrequent beneficial new traits generated by recombination presumably promote evolutionary success, just as infrequent beneficial mutations do.

5.2 Sexual Communication in Fungi, Primarily for DNA Repair, but Also for Limited Complementation

1. *Sexual communication in fungi*. Among eukaryotic microorganisms, pheromones promote sexual interaction in many species. These simple eukaryotes use a variety of molecules, such as steroids, other lipids, peptides, and derivatives of organic acids, as well as large molecules such as glycoproteins as sex pheromones. Although these sex pheromones are usually transmitted through an aqueous medium, they may also be transmitted through the air as in the fungus *Mucos mucedo*.

2. *Sexual communication in yeast*. The sexual cycle and communication have been especially well described in the yeasts *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*. Mating in these yeasts occurs between two cells of opposite mating type and is facilitated by the reciprocal action of pheromones. Cells of each mating type release pheromones that induce mating through promotion of specific modifications in cells of the opposite mating type. The two cells then conjugate, forming a diploid zygote that can undergo meiosis. This leads to sporulation and release of ascospores that can germinate to form haploid vegetative cells, thus completing the life cycle. The pheromones produced by these yeasts are short peptides.

The results of several studies bear on the adaptive advantage of the meiotic events promoted by these sex pheromones. Recombinational repair of DNA double-strand breaks occurs during meiosis in *S. cerevisiae* and *S. pombe*. The *rad51* and *dmc1* genes of *S. cerevisiae* are homologs of the *recA* gene of *E. coli*. A homolog of *E. coli* RecA also occurs in *S. pombe*.

It was found that treatment of *S. pombe* with H_2O_2, a DNA-damaging agent, caused increased mating. This stimulation of mating can be interpreted as an adaptation to promote recombinational repair of the introduced DNA damages. Thus, in *S. cerevisiae* and *S. pombe*, production of sex pheromones appears to be an adaptation for promoting recombinational repair of DNA, ''Level 1'' of sexual communication, as in bacteria.

In *S. pombe*, the mating pheromones M-factor (produced by the ''Minus'' mating type) and P-factor (produced by the ''Plus'' mating type) ensure sexual interaction of cells of opposite mating type. However, during vegetative growth, a cell of one mating type switches to the other mating type in about every two generations. Similarly, in *S. cerevisiae*, haploid descendants from spores of one mating type can change their mating type frequently so that after several cell divisions a diploid population develops from a single haploid spore. These observations indicate that inbreeding is avoided to some extent in *S. cerevisiae* and *S. pombe*, since mating with an individual of the opposite mating type is required, but that it is not strongly avoided since a cell of one mating type can give rise to a cell of the opposite mating type frequently, and then sibling cells can mate.

In *S. cerevisiae* and *S. pombe*, the diploid stage of the sexual cycle, formed by mating, probably expresses functions necessary for meiosis and sporulation. Recessive mutations in the genes encoding these functions may explain the observation that

inbreeding is avoided to some extent. We discussed above (Section 3.4) that the diploid stage of a life cycle serves the adaptive function of complementation, or the masking of deleterious recessive mutations. Optimal masking is achieved when the diploid zygote is formed from the union of haploid cells of two genetically unrelated individuals, so that the recessive mutations carried by each genome are most likely to be different. However, relatively few functions are probably expressed specifically in the diploid phase of *S. cerevisiae* and *S. pombe*, and this might explain why the masking of deleterious recessive mutations is only weakly promoted in these organisms.

In these yeasts, the pheromones operate at "Level 2" as well, to promote "outcrossing," in addition to acting at "Level 1" to promote mating between individuals.

3. *Sexual communication in neurospora.* *Neurospora crassa* is an ascomycete, like the yeasts *S. cerevisiae* and *S. pombe*, but its sexual phase is more elaborate than those of yeasts. *Neurospora crassa* encodes a gene *mei3*, which is homologous to *E. coli recA* and *S. cerevisiae dmc1* and *rad51*. A mutant defective in *mei3* has reduced repair of DNA damage and, when homozygous, is blocked in the zygotene stage of meiotic prophase. This implies that *N. crassa mei3*, like *S. cerevisiae dmc1* and *rad51*, is required for recombinational repair of DNA damage during meiosis.

Neurospora crassa has two stable mating types which produce sex pheromones. The sex pheromone of one mating type induces the formation of the female sexual structure, the differentiated protoperithecium, in the opposite mating type. Once a protoperithecium is formed, the vegetative conidiospores or mycelia of the opposite mating type can act as the male partner. Upon mating, a diploid nucleus is formed by fusion of male and female nuclei of opposite mating type. This diploid nucleus then undergoes meiosis, followed by mitosis, to produce eight ascospores. Each set of eight spores is enclosed within a sac, referred to as an *ascus*, and many asci are contained within the mature fruiting body, termed a *perithecium*. Genes promoting ascus and ascospore maturation, as well as perithecium development are expressed in the diploid stage. It was found that 74 of the 99 wild-collected *N. crassa* isolates from 26 populations carried one or more recessive mutations in genes that expressed in the diploid stage. They estimated that the number of genes expressed in the diploid stage is at least 435. Mutations in these genes, when homozygous in the diploid stage, cause formation of aborted asci, ascospores with maturation defects, or barren fruiting bodies with few sexual spores. The evolution of two distinct mating types, which communicate via pheromones, inhibits inbreeding in *N. crassa*, and this provides the advantage of masking recessive mutations in the numerous genes that express in the diploid stage.

Overall, in fungi, it appears that pheromones act at both the primary level of sexual communication to promote sexual interaction for meiotic recombinational repair and the secondary level to promote outcrossing, which allows masking of deleterious mutations.

5.3 Sexual Communication in Higher Eukaryotes, Primarily for Complementation while Repair Is an Automatic Concomitant of Sexual Reproduction

1. *Flowering plants.* Since the diploid stage is the most prominent stage in the life cycle of flowering plants, the advantages of complementation should be large. Thus,

the investment in sexual communication to promote cross-fertilization, as the most common mode of reproduction among flowering plants, is probably due to the prominence of the diploid stage and the benefit of masking deleterious mutations. Instances in which outcrossing has been abandoned in favor of self-fertilization or parthenogenesis may be explained by the need of some plants to survive in sparse populations in which the costs of sexual communication would be prohibitively high.

Sexual signals in plants promote mating, but the subsequent meiosis and recombinational repair happen in the succeeding generation when the progeny produce germ cells. Among those flowering plants that depend on cross-fertilization to reproduce, sexual communication acts at both the primary and the secondary level. However, in plants that can undergo self-fertilization, sexual communication is unnecessary when this option is used.

2. *Vertebrates.* In bacteria, fungi, and protozoa, sexual reproduction is generally facultative and favored only under certain conditions. In nearly all vertebrates, however, the sexual cycle is obligatory, and thus sexual communication is ordinarily necessary for reproduction.

In vertebrates, meiosis and concommitant recombinational repair ordinarily occur at a time separate from sexual signaling. However, sexual signaling to attract a mate is essential to continue the sexual cycle, which includes fertilization, production of progeny, and further meioses. Thus, sexual signals promote mating, but meiosis and recombinational repair occur subsequently in the succeeding generation, when progeny form germ cells.

Among vertebrates, sexual communication for promotion of outcrossing has been studied in many systems. In toads, advertisement vocalizations given by males apparently serve as cues by which females recognize their kin and thus avoid inbreeding.

In mouse, mating preference is strongly influenced by the major histocompatibility complex (MHC) genotype. A mouse can distinguish close relatives from more distantly related mice on the basis of MHC genotype through their sense of smell. Using this device, mice tend to outcross, avoiding mating with close relatives. Inbreeding of mice derived from wild populations has a significant detrimental effect on survivorship when the mice are reintroduced into a natural habitat. This effect is even more severe than that observed in laboratory studies of the population. In the other vertebrates, to be described below, the communication processes used to promote outcrossing have not been as well defined as in the mouse. Nevertheless, we infer that analogous processes also exist in these cases.

Outcrossing is promoted among birds. The great tit (*Parus major*) is a monogamous woodland bird. In natural populations, outcrossing is promoted by the dispersal of daughters, but not sons. Furthermore, among infrequent incestuous matings, nestling mortality was nearly double that of outbreeding pairs.

Among primates, avoidance of inbreeding occurs in rhesus monkeys, chimpanzees, and gorillas. Juvenile rhesus monkey males leave the troop that they were born into when they mature. This pattern is similar to that in many mammals in which male progeny leave the social group into which they are born and find a mate in another group. Chimpanzees and gorillas follow a less common pattern in which the female, rather than the males, leave their natal group and transfer to other groups.

Inbreeding ordinarily is avoided in humans. In humans, body odor preferences (determined by men and women scoring the odors of T-shirts previously worn by men or women) would serve to increase heterozygosity in the progeny. Prohibitions against marriage and sexual relations between close relatives are a near universal feature of human social behavior in many different cultures. This general prohibition is known as the incest taboo.

The basis for the incest taboo appears to be the avoidance of inbreeding because of the effect of the expression of deleterious mutations. There is a significantly higher incidence of major congenital malformations and postnatal mortality among the progeny of consanguineous marriages than among the progeny of nonconsanguinous marriages.

We have reviewed the evidence that ''Level 2'' of sexual communication, to avoid inbreeding and promote outcrossing, is common in vertebrates. Since sexual interaction in vertebrates is usually essential for reproduction, sexual communication at ''Level 1'' for sexual interaction is ubiquitous.

5.4 "Level 3" of Sexual Communication Is Used to Select for Fitness among Potential Mates

In addition to ''Level 1'' and ''Level 2'' functions of sexual communication, the first to promote homologous recombinational repair and the second to promote outcrossing, a third aspect of sexual communication involves courtship behavior. The adaptive function of courtship probably is selection of a mate with the characteristics that optimize reproductive success (selection for fitness). This leads to competition among individuals of the same gender. Such competition is the basis for sexual selection, regarded as having molded many features of animal behavior.

As an example, females of the guppy fish, *Poecilia reticulata*, respond more strongly to the mating displays of male guppies which have brighter orange spots. The brightness of the spots correlates positively with health and vigor and negatively with previous parasitic infection. Thus female guppies tend to select healthier mates that are more resistant to parasites.

Substantial evidence has been presented on human courtship behavior suggest that the basic biologic function of human courtship is to optimize reproductive success by the selection of a mate of the highest possible fitness.

6 Overview

The occurrence of high levels of endogenous DNA damage in mammals is now well established. DNA of mammalian somatic cells is the master informational molecule, and accumulated damages in this molecule probably cause the progressive irreversible deterioration of cell, tissue, and organ function that defines mammalian aging. When an organism forms progeny via germ cells, it is important that these cells be free of DNA damages, since such damages cause inviability. To facilitate efficient DNA repair, the redundant information available in the diploid cell can be used to replace damaged information through recombinational repair. Sexual reproduction appears to be an adaptation to promote pairing and exchange between homologous chromosomes for the purpose of efficient repair of the DNA, which is passed on to germ cells. In eukaryotes this occurs during meiosis,

while in bacteria and viruses it occurs during less complex, but similar, processes.

Mutations are another type of error in DNA in addition to damage. Unlike damages, mutations cannot be recognized by repair enzymes. Mutations, however, can be masked when information from two unrelated individuals (parents) is brought together through fertilization to form the progeny zygote. Thus, the outcrossing aspect of the sexual cycle in diploid organisms appears to be maintained by the advantage of masking mutations. Overall, aging appears to be a consequence of the accumulation of DNA damage, and sex appears to be an adaptation for the removal of damage through enhanced recombinational repair and the masking of mutations through outcrossing.

Sexual communication probably arose in bacteria as an adaptation to promote DNA transfer in order to allow recombinational repair of damages in DNA. Sexual communication is probably maintained in organisms with a distinct diploid stage of their life cycle by (1) the advantages of recombinational repair during meiosis, (2) outcrossing that facilitates complementation of recessive deleterious mutations, and (3) mate selection for fitness.

Keywords

HIV (Human Immunodeficiency Virus)
A retrovirus of the lentivirus family responsible for AIDS.

AIDS (Acquired Immune Deficiency Syndrome)
A clinical state of profound susceptibility to infection with low pathogenicity (opportunistic) infectious agent and unusual malignancies.

Retrovirus
A virus characterized by a diploid RNA genome converted to a DNA provirus by its reverse transcriptase enzyme and integrated into the target cell DNA.

Provirus
The integrated DNA form of the virus.

Antiretroviral Drugs
Pharmacological agents targeting virus-specific processes used in the treatment of AIDS.

This article describes the basic molecular biology of the viruses causing AIDS and the nature of the disease in causes, summarizing the immune response, antiviral therapy and varrine prospects.

1 Origins of HIV

HIV is a retrovirus of the lentivirus family. Closely related viruses have been discovered in many groups of African primates and sequence comparison would suggest that there has been more than one transspecies transmission of these viruses from monkeys into humans within the last 80 years. In the simian population, these viruses are transmitted by blood contact during biting and fighting. The butchering of monkeys for sale as bush meat is a highly plausible route of transmission of these viruses into humans through monkey blood contamination of cuts and scratches on human hands. Hypotheses surrounding contaminated polio vaccine have been comprehensively disproved.

There are two major divisions of HIV that have infected humans, HIV-1 and HIV-2. HIV-1 is phylogenetically closely related to SIV_{cpz}, a lentivirus of chimpanzees. HIV-2 is different in sequence from both of these and more closely related to the sooty mangabey lentivirus, SIV_{smm}. HIV-1 is divided into a number of different groups, the main (M) and the out (O) and new (N) groups within each of which are clades. The M group is estimated to have entered the human

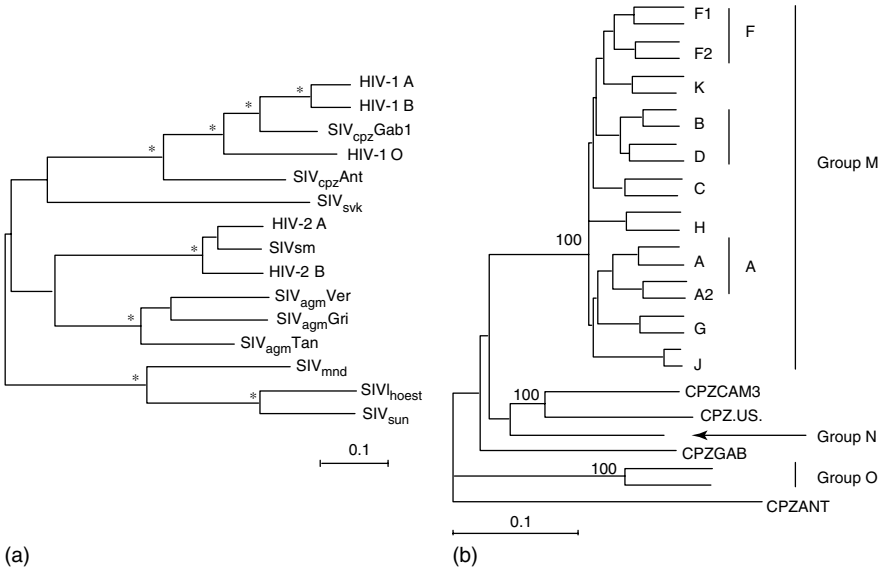

Fig. 1 (a) Relationships of HIV and SIV based on *pol* sequence comparison and (b) clades of HIV.

race in the 1930s. Within the M group, nine clades are recognized (Fig. 1a and b). In addition to clades, many recombinant or ''mosaic'' subtypes have also been identified. HIV-1 and HIV-2 have a very similar genetic structure except as detailed below. The sequence of the virus is, however, very variable indeed and two clades within the M group may differ in certain regions of the genome at the amino acid level by 20 to 40%. This is an astonishing level of variation and contributes significantly to the virus' success in establishing infection in the human population.

In their native hosts, simian lentiviruses appear to cause little disease. SIV from the African green monkey, SIV_{agm}, is asymptomatic in its natural host but produces profound immunodeficiency when introduced into rhesus macaques or cynomologus macaques. This may give us clues to the reason why HIV is so catastrophic in humans given the short time (<100 years) that it has been infecting humans and the consequent lack of host or pathogen adaptation.

The name lentivirus (lenti = slow) is derived from the archetypal member of this family, Maedi-Visna virus, which infects sheep and causes a very slow progressive disease involving pneumonic change and wasting, sometimes associated with central nervous system defects. In HIV, there may be symptoms associated with the initial viremia but thereafter, the speed of onset of clinical disease following infection is variable and infected individuals may remain asymptomatic for a number of years before the immunodeficiency becomes severe enough to cause illness.

Both HIV-1 and HIV-2 infection lead to a progressive decline in immune competence to the point where it becomes incapable of protecting the individual from otherwise very low pathogenicity infections, which are easily dealt with by a normal individual. This progressive loss of immune competence has given

the disease its name, *acquired immune deficiency syndrome* (*AIDS*). In general, the tempo of the disease is slower with HIV-2, possibly related to its replicating to a lower titer. This may also explain why it is less easily transmitted vertically from mother to child than HIV-1.

2 The Molecular Biology of HIV

Understanding the interactions of the virus with the immune system, its ability to cause disease, and potential therapies requires an understanding of the retroviral life cycle. The genetic structure of the virus is shown in Fig. 2. It has the conventional *gag*, *pol*, and *env* open reading frames of all retroviruses together with at least seven additional accessory and regulatory genes.

2.1 Virus Structure

HIV is a conventionally structured retrovirus (Fig. 3) with a C-type assembly mechanism. On the exterior, it has a lipid envelope derived from the surface plasma membrane of the cell from which it budded and in this are the envelope glycoproteins consisting of trimers of a transmembrane (TM) protein, each of which is noncovalently linked to an external surface (SU) glycoprotein. TM and SU are often referred to by their molecular weights as gp41 and gp120 respectively (in HIV-1).

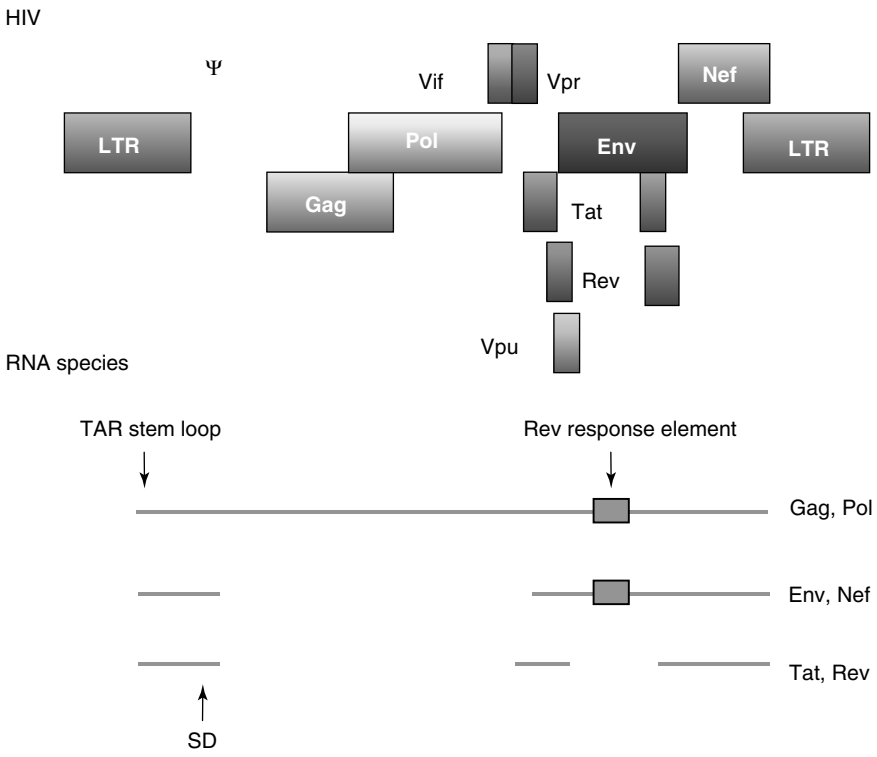

Fig. 2 Genetic structure of lentivirus DNA provirus and families of RNAs transcribed.

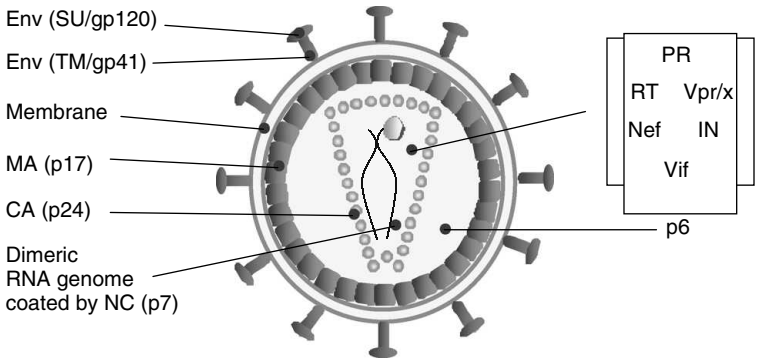

Fig. 3 Diagram of HIV 1 virus particle.

Within the mature virus particle, the inner surface of the envelope is lined by the matrix protein (MA), a cleavage derivative of the major core polyprotein, Gag. Within this is a pyramidal core structure made up of capsid (CA) protein subunits. This encloses the two copies of the RNA genome that are coated with the nucleocapsid (NC) protein. The two RNAs are tightly linked at a site known as the *dimer linkage site* (DLS). Each has a cell-derived $tRNA_{lys}$ annealed to a complementary sequence at the 5′ end of the genome, the primer binding site. Within the particle are a number of viral accessory proteins including Vif and Vpr. The virus also captures a number of cellular proteins including glycoproteins from the plasma membrane of the cell in its envelope and a number of cytoplasmic proteins including cyclophilin that binds specifically to the capsid protein in the core. The viral gene products of the *pol* gene are also incorporated into the virus. These include the protease (Pro) that cleaves the Gag and Pol precursor polyproteins to generate Gag products (p6, p7, p17, and p24) and Pol products including the reverse transcriptase enzyme (RT), which is responsible for generating a DNA copy from the RNA genome and the integrase enzyme (IN) that inserts the viral DNA into the chromosomes of the target cell.

2.2 Life cycle

Infection of a cell by HIV occurs following binding of the virus through its SU glycoproteins to the cell surface molecule CD4 and coreceptors (Fig. 4). The CD4 glycoprotein is found on a variety of cells, predominantly in those of the immune system. HIV tropism is broadly divided into viruses that can infect T lymphocytes (T-cell tropic) and those that infect cells of the macrophage/monocyte lineage (M tropic) (see Sect. 2.4).

Binding to the cell is followed by a conformational change in TM in which its hydrophobic terminus penetrates the target cell membrane and approximates it to the viral envelope lipids, fusing the two membranes together. Cellular lipid rafts appear to play a role in virus entry. The capsid and its contents enter the cell cytoplasm and the processes of disassembly and reverse transcription begin in which the viral RNA is copied into a DNA form. Reverse transcription is shown in Fig. 5. More detailed accounts can be found in the literature. Two important features of the

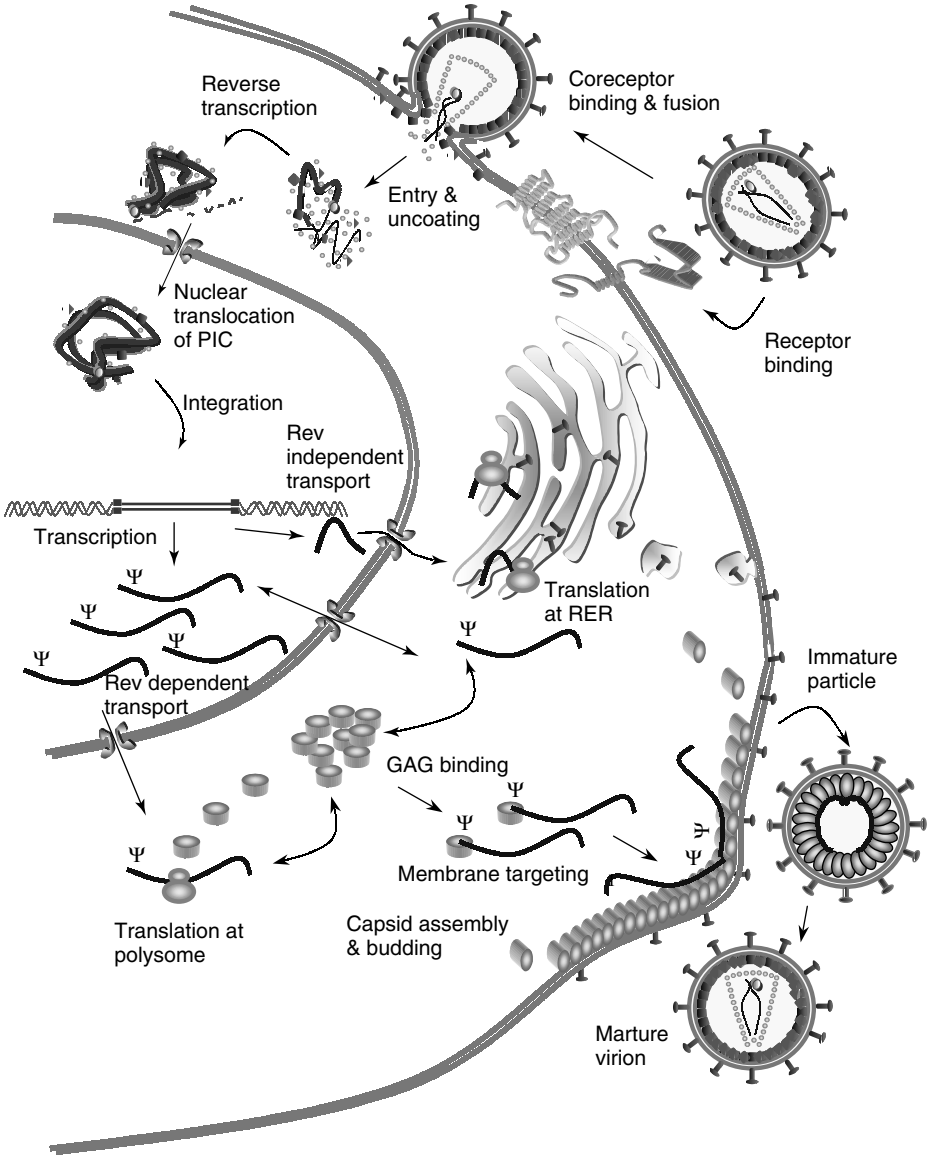

Fig. 4 Retroviral life cycle.

reverse transcription process are that both the RNA genomes are used as a template to produce a DNA copy in which template switching can occur such that the resultant DNA may be a combination of copies of segments from each of the RNA strands. Secondly, the resulting double-stranded DNA terminal sequences have both been templated by the 3′ long terminal repeat. It is during this reverse transcription step that the combination of template switching and nucleotide misincorporation, due

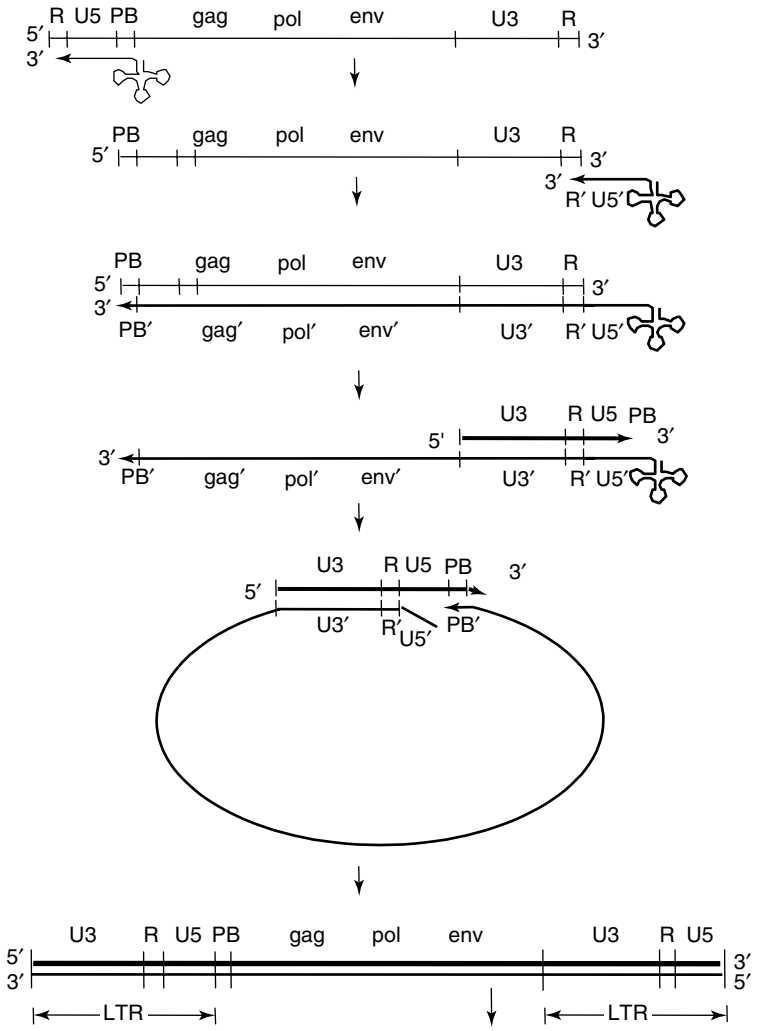

Fig. 5 Reverse transcription.

to the lack of RT proof-reading, produces the remarkable sequence diversity seen in HIV.

The DNA provirus is transported into the nucleus as a preintegration complex (PIC) using karyophilic signals found on proteins with the complex including the matrix protein, the integrase, and the Vpr accessory protein. There is some functional redundancy between these signals. In lentiviruses, the PIC can cross an intact nuclear membrane, meaning that these viruses have the unique capability among retroviruses of being able to integrate into cells that are not undergoing mitosis. The integration step involves the integrase enzyme cleaving the cellular DNA and making a 3′ to 5′ recess in the two ends of the proviral DNA. The chromosomal DNA undergoes a similar staggered

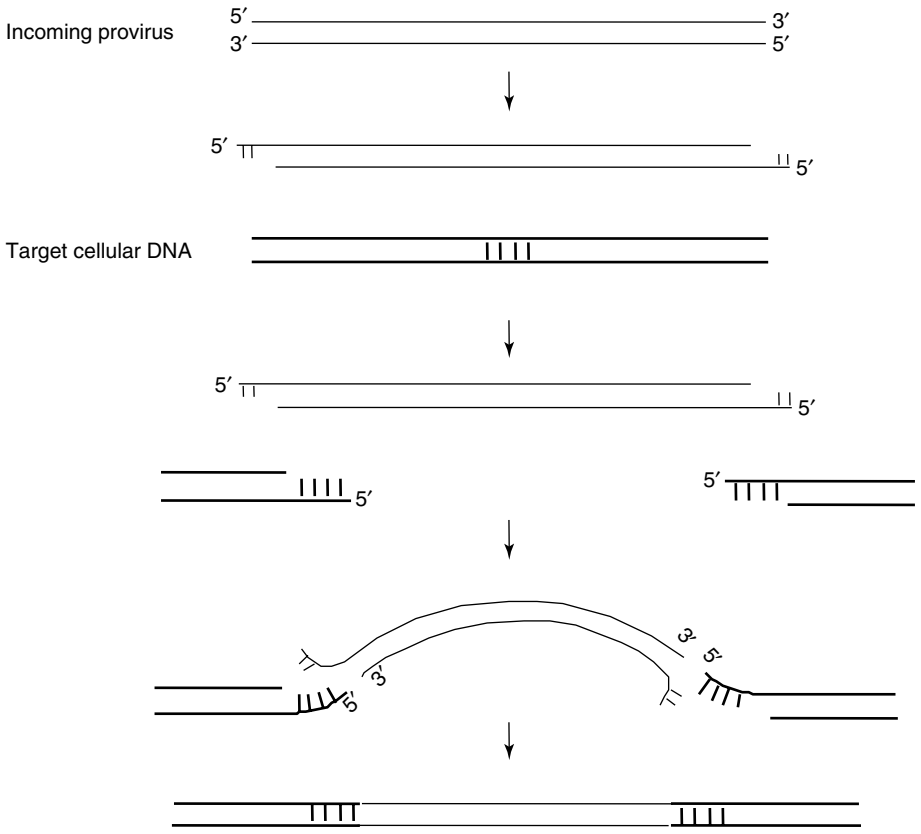

Fig. 6 Integration process.

cleavage and the viral and cellular DNA ends are linked. Cellular enzymes fill in the defect (Fig. 6). The resulting sequence shows a reduplication of the cellular nucleotides at either end of the provirus.

The integrated provirus may remain transcriptionally silent. Transcriptional activation depends in part on the degree of stimulation of the cell. In T cells, for example, mitotic stimulation is associated with activation of the retroviral promoter. Viral latency is a useful strategy for this pathogen to escape immune recognition and studies suggest that, at any one time, probably less than 10% of infected cells have a transcriptionally active virus.

The 5′ long terminal repeat of the virus contains a promoter element with a conventional TATA box. When activated, this is transcribed by RNA polymerase II to produce a genome length transcript. Multiple small abortive transcripts are seen early on but sufficient full-length RNAs are produced to initiate gene expression. Instability sequences are found in the full-length RNA, which default the RNA transcript to be spliced, and intronic sequences encompassing the Gag and Pol regions and the central part of envelope are spliced out to produce multiply spliced RNAs that are then exported into the cytoplasm and translated on free cytoplasmic

ribosomes. The earliest transcripts code for the regulatory proteins, Tat, Rev, and Nef (Fig. 2). Tat is a transcriptional activator that shuttles back into the nucleus and interacts with an RNA stem loop structure, the Tat Response Element (TAR) at the 5′ end of all viral transcripts (Fig. 2). Tat bound to TAR, recruits cyclin T and CDK9, which cause hyperphosphorylation of the C-terminal domain of the RNA polymerase II, massively enhancing its transcriptional efficiency. The sequence of transcription, export, and translation is replicated and amplified and more Tat protein is produced in what amounts to a positive feedback loop. The spliced RNA species encoding Rev is also translated and like the Tat protein, it shuttles back into the nucleus. It interacts with an RNA structure called the *Rev Responsive Element* (*RRE*) in the envelope intron (Fig. 2), enhancing export of both the full-length genomic RNA and the singly spliced RNA that encodes the envelope glycoprotein. Thus, the Tat protein causes an early amplification of transcription, and Rev subsequently leads to an early to late shift in the species of RNA, which are exported from the nucleus from those encoding regulatory factors to mRNAs for structural and enzymatic proteins. Unspliced full-length RNAs are translated on free cytoplasmic ribosomes to produce the Gag and Pol proteins. The singly spliced envelope encoding RNA binds to a ribosome and with the translation of its signal peptide, the complex is transported to the rough endoplasmic reticulum where envelope glycoproteins are translated and glycosylated using the conventional cellular glycoprotein secretory route.

The Gag and Pol proteins are encoded on the same transcript but in different reading frames. Translation of the polyprotein is interrupted by a frameshift sequence at the Gag/Pol overlap with an efficiency of about 5%. The ribosome shifts into the −1 frame, so that for approximately every 19 Gag proteins that are produced, 1 Gag/Pol fusion protein is synthesized. Gag and Gag/Pol proteins assemble at the plasma membrane in approximately the same stoichiometric ratio. At some stage, following transcription, the Gag protein has interacted with full-length genomic RNA transcripts and captured these through binding to a complex folded region of the RNA termed the *packaging signal* or Ψ region. This RNA is then transported into the assembling virion where it binds other Gag proteins through the zinc fingers of their nucleocapsid subfragments, the RNA acting to some extent as a scaffold for viral assembly. RNA–protein and protein–protein interactions contribute to the generation of a convex curved raft of protein underneath the cell membrane. Assembly continues with the viral bud bulging out of the cell and the Gag and Gag/Pol proteins accumulating to form a spherical viral core. This mode of assembly at the membrane defines lentiviruses as having a C-type morphology.

The viral core that forms is composed of Gag and Gag/Pol polyproteins, all aligned with the matrix region outermost and the NC region toward the center of the particle. At the extreme C-terminal of the Gag protein is a small region termed p6, which is intimately involved in the budding process. Mutations in p6 have been shown to lead to arrested budding in which stalked but otherwise intact particles remain attached to the plasma membrane of the cell. p6 has recently been shown to interact with a cellular protein, TSG101. In the normal cell, TSG101 is involved in the budding process of endosomes into multivesicular endosomes. It appears that the virus has

hijacked this budding mechanism for an external budding process and uses the same cellular factors to facilitate this. The complete array of proteins involved is not yet elucidated.

After or during the process of budding, the protease component of the Gag/Pol polyprotein becomes activated. This enzyme is inactive in the Gag/Pol monomer and functions as a homodimeric molecule. An as yet unknown process appears to approximate two protease monomers leading to autolytic cleavage of the first protease enzyme, following which cleavage of further Gag/Pol molecules will lead to release of further protease subunits and a cascade of proteolytic cleavage of Gag and Gag/Pol can occur. This cleavage is accompanied by a morphological change in which the particle changes from a spherical one containing a ''doughnut'' ring of structural proteins into a typical retrovirus particle with matrix protein underlying the envelope and an apparent space between this and the pyramidal core, which is composed of capsid proteins.

2.3 Additional Accessory Proteins

These can be divided into those that are or are not incorporated into the viral particle.

2.3.1 Virion Associated Proteins

As noted previously, the Vpr protein is involved in the preintegration complex targeting the nucleus of the newly infected cell. There is evidence that Vpr binds to the nucleoporin hCG1. Vpr also appears to have other functions. It may be a transcriptional transactivator in its own right through binding to p300/CBP coactivators. It has also been implicated in G2 phase cell cycle arrest. This is suggested to be the phase of the cell cycle at which Tat transactivation is most efficient. Vpr may also have a role in pathogenesis of AIDS since it has clearly been associated with apoptosis in a number of different cell types including neurons. It appears to gain entry to the virus by binding to the p6 region of Gag.

In HIV-2 and SIV, a gene duplication appears to have occurred to produce a second regulatory protein, Vpx, with homology to Vpr. There is evidence that in these viruses, Vpx may have subsumed the specific nuclear entry role of Vpr.

Vif is another small accessory protein that is incorporated into the virus particle. It has been clear for many years that Vif is an essential protein for viral replication in some cell lines but not others. The Vif phenotype depends on virion associated Vif since expression of Vif in a target cell does not appear to allow replication of an incoming Vif negative virus. Recent work suggests that Vif may be interacting with an inhibitory cellular protein that has sequence homology to proteins of the cytidine deaminase family and it may be that the actions of this nucleotide-modifying enzyme must be neutralized for successful reverse transcription and integration to occur.

2.3.2 Nonvirion Associated Proteins

Vpu is a small protein found only in HIV-1 and SIV_{cpz}. It has a number of roles that enhance the efficiency of budding of the virus. The envelope glycoprotein, gp120, which on the virion particle interacts with the CD4 protein, is synthesized and exported in the infected cell through the same pathway as the cell's own CD4. Complexing of these two molecules in the ER has been documented. Vpu appears to facilitate disaggregation of these two by binding to and degrading CD4, enhancing the export of the gp120 SU protein.

Vpu also appears to have additional envelope-independent effect, enhancing virus export.

The Nef protein is found throughout the primate lentiviruses. It is a multifunctional molecule. It has been documented as being capable of downmodulating cell surface expression of certain cellular proteins including CD4 and the MHC proteins. Recent evidence suggests that Nef may be involved in recruiting lymphocytes to HIV-infected macrophage/monocytes. Specific effects on migration inhibition of lymphocytes have been documented and these properties seem to be a powerful functional argument for Nef having important effects on virus spread and infectivity. This is further supported by the observation that Nef-deleted or Nef-mutated viruses have been shown to be associated with a severely attenuated pathogenicity. Recipients of HIV-infected blood from a single donor in Australia remained well for many years and the virus was identified as having a defective Nef protein. In SIV infection, Nef mutant viruses show an attenuated phenotype and reversion of the Nef mutation to wild type is associated with a regain of virulence.

2.4 Envelope Variants

The envelope gene of HIV-1 encodes a polyprotein comprising the two components of the external viral receptor ligand. At the N-terminus is the surface (SU) or gp120 protein. At the C-terminal, the TM is found. This latter sequence contains a hydrophobic stretch of amino acids, which comprise the membrane anchor and a second hydrophobic region involved in binding to the target cell membrane and fusing it with the virus envelope. The SU region is divided into five constant (C1-5) and five variable (V1-5) regions. The SU protein of HIV is responsible for binding to target cells. The V3 loop region of SU has attracted much attention because of its critical importance in receptor binding. The CD4 protein found on lymphocytes and cells of the monocyte/macrophage series was identified early in the AIDS epidemic as being a major receptor for the virus. At the same time, it was clear that binding to CD4 was necessary but not sufficient for infection. Observations that activated lymphocytes released substances that block infection by HIV and the identification of these as chemokines and their receptors as belonging to the family of 7-transmembrane spanning chemokine receptors revealed the existence of a family of coreceptor molecules, which are required for successful entry and infection. The two major families of these are the so-called *CC chemokine receptors* and the *CXC receptors*. Two of these are the principal HIV receptors. The CC chemokine receptor CCR5 responds to the cytokines MIP1α, MIP1β, and RANTES. The CXC chemokine receptor CXCR4 is bound by SDF1. There are a number of other receptors that have been identified as being involved in binding of HIV-1, HIV-2, and SIV. The identification of these receptors neatly mapped on the long-standing observation that there were at least two types of tropism identifiable in HIV. Some viruses appeared to be able to infect cells of the monocyte/macrophage series very efficiently but were very poor at infecting T lymphocytes. Others appear to be extremely efficient at infecting T lymphocyte cell lines *in vitro* but were very poor at infecting macrophages. These were broadly divided into ''macrophage tropic'' and ''lymphocyte tropic'' viruses (although this is a simplification). The chemokine receptor data link these tropisms with the

fact that the lymphocyte tropic viruses have a surface envelope protein that preferentially binds to the CXCR4 receptor and the macrophage tropic to the CCR5 receptor. These tropisms are commonly abbreviated by describing viruses as X4 or R5, respectively. More recently, a mutation has been identified, which affects about 1% of Caucasians who are homozygous for a stop codon causing a truncation of the CCR5 protein, and renders these individuals uninfectable by macrophage tropic virus. This explained another observation that there were some individuals who appeared to be repeatedly exposed to HIV through high-risk sexual practices and yet did not become infected.

3 Routes of Transmission

Infection can occur via cell-free virus or through contact between infected cells and those of the recipient. SIV in monkeys is probably primarily transferred from host to host by blood contact. HIV is also infectious by blood contact but the predominant mode of transmission is by the sexual route. HIV positive mothers can transmit the virus to their newborn child at birth or through breast feeding. The fact that cell-free virus is infectious means that HIV was transmitted very efficiently in clotting factor concentrates in the 1980s, resulting in the infection of large cohorts of hemophiliac patients. In the developed world, blood donations are screened for HIV as they are in many countries in the developing world. There is a very small but finite risk that a blood donor in the ''window'' period before seroconversion may transmit an infection through blood donation but this is in the order of less than one in a million. Blood transmission occurs quite efficiently in the case of intravenous drug users who share needles. Sexual transmission can occur from both male to female and female to male with an estimated risk of 1 : 200. Mucous membrane transmission probably begins with the infection of sessile cells of the macrophage/monocyte system in the mucous membrane tissues with subsequent replication and spread of virus to other cells of the immune system. Recent evidence implicates Langerhans cells as the first target. These may bind the virus using the DC-sign cell surface lectin, which has a high affinity for gp120. Whether replication occurs within these cells or whether surface-bound virus infects migrating T cells and macrophages is not established.

4 Natural History of Infection

The characteristic natural history of infection is illustrated in Fig. 7. Following early replication in lymph nodes and within a period of approximately four to eight weeks after exposure to virus, viremia becomes detectable in the form of ELISA positivity to the p24 capsid antigen and detection of viral RNA in the serum. This viremia rises rapidly to a peak that may be around five million copies of the viruses per milliliter of blood. At this time, the beginnings of an immune response against the virus become detectable, including special antibodies directed against the viral proteins. Subsequently, the virus level in the blood falls to a ''set point'' and this correlates most closely with detection of a rise in the cytotoxic T lymphocyte cell mediated immunity. At the time of this seroconversion, between a third and a

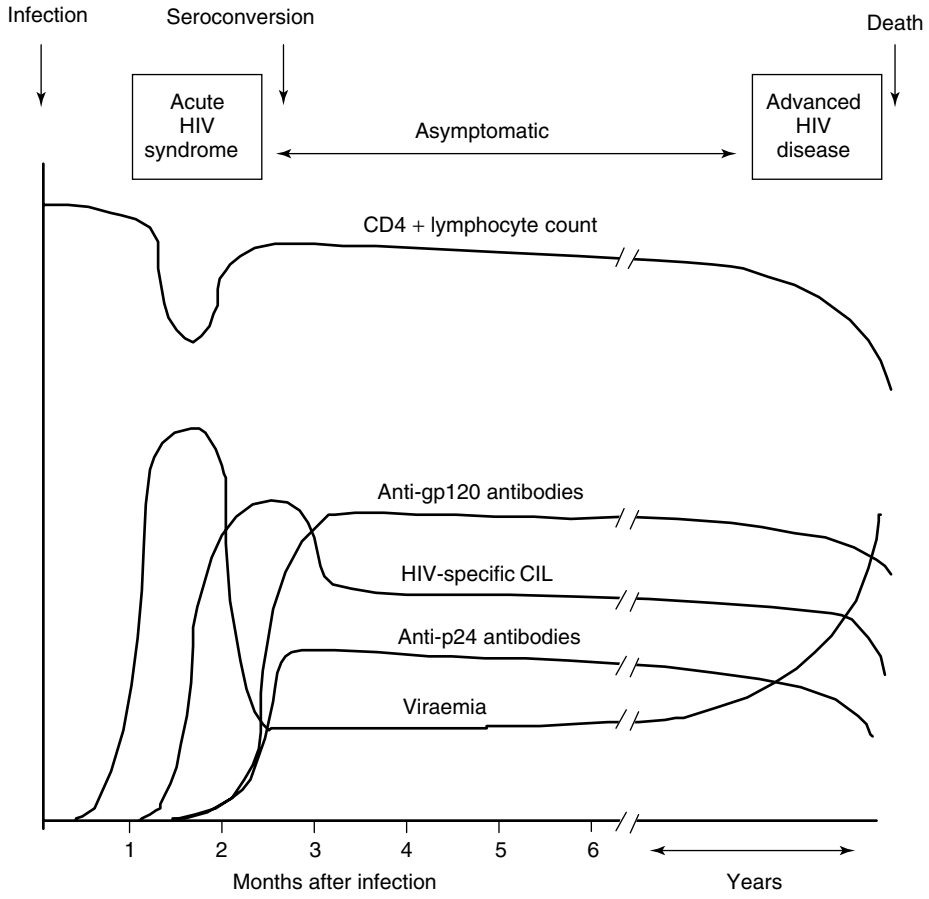

Fig. 7 Natural history of HIV infection.

half of infected patients will have symptoms resembling a glandular feverlike illness with lymphadenopathy, transient petechial rashes, arthropathy, evidence of peripheral neuropathy, and occasionally a brief meningoencephalitic illness. However, virtually without exception, these symptoms resolve. There then follows a period of apparent stability in which the viral level or ''viral load'' remains stable and there is ongoing evidence of an immune response. In some individuals, persistent enlargement of lymph nodes occurs associated with weight loss and fevers. This so-called *persistent generalized lymphadenopathy* appears to be associated with a worse prognosis in terms of the speed of onset of immunodeficiency. Despite the asymptomatic nature of infection in most individuals at this stage, measurements of the CD4 lymphocyte count show that during the initial viral peak, there is a corresponding trough in lymphocyte numbers, implying a significant amount of direct virus mediated lymphocyte destruction. This rises again as the virus load is brought under control but does not achieve the preinfection level and

from then on there is a very slow but progressive decline.

Calculations of the quantity of virus being produced during this time and the rate of lymphocyte destruction/regeneration have generated the remarkable figures that around 10^9–10^{10} viruses are produced and destroyed each day. This is probably an underestimate. The lymphocyte turnover is also around 10^9 per day, but while the viral load may be constant or may rise, the lymphocyte count slowly falls such that there is a net loss of around 10^6 lymphocytes per day. The fall in lymphocyte count correlates with a progressive decline in immunological competence and is a marker, if not the cause, of the eventual breakdown in immune competence. At this stage, the number of infected cells in the blood is very low, at around 1 in 10^5. This might suggest that virus mediated lymphocyte destruction is less important at this stage, although localized destruction in lymph nodes would be difficult to detect. Immune clearance of infected cells, however, may be the dominant force affecting lymphocyte numbers. Depending on the success of the immune response in controlling the virus, the length of time between seroconversion and immunodeficiency may be anything from 2 up to 12+ years. However, as yet, although there are examples of very slow progressors, there is no evidence of complete control of viral infection by the immune system once the virus has established itself. At the late stages of the disease, the predominant type of virus appears to change with the emergence of faster replicating T-cell tropic (X4) variants.

Symptomatic immunodeficiency becomes apparent when the lymphocyte count falls below $200 \times 10^9\ L^{-1}$, at which point the individual is at very high risk of opportunistic infection and the development of unusual malignancies. The fall in lymphocyte count correlates with a loss of control over viral replication and a rise in detectable virus in the circulation in the absence of antiretroviral therapy. Death from an overwhelming infection or an uncontrolled malignancy usually occurs within two to three years of the onset of the severe immunodeficiency even with treatment of the individual infections and cancers.

As will be described later, the advent of antiretroviral therapy has transformed the natural history of disease in the western world. Pharmacological control of virus replication leads to a fall in viral load and a corresponding rise in the CD4 lymphocyte count. This leads to a reversal of the loss of immunocompetence, which, although it may not be complete, is enough to significantly reduce the risk of opportunistic infection.

5 Immune Response to HIV

Following the initial peak of virus in the circulation after infection, the viral load declines to a set point, which, on average, is around 30 000 copies per milliliter. If it is higher than this, the onset of AIDS is quicker and vice versa. It appears that qualitative and quantative parameters of the immune response determine this set point. A broad antibody response develops within the first three months of infection with specificity for some of the structural proteins such as Gag. Antibodies to Envelope and Polymerase proteins appear swiftly thereafter, and the regulatory and accessory proteins also trigger an antibody response.

Antibodies interfering with interaction between the envelope protein and the

cellular receptor may be neutralizing and the site at which they bind on the viral protein provides strong clues as to the important regions of SU involved in viral entry. In particular, the V3 loop is a major target for neutralizing antibody. A second region on gp120, which is involved in both CD4 and chemokine receptor binding, is another neutralization target. However, V3 loop neutralizing antibodies often appear to be more effective against laboratory strains of HIV than primary clinical isolates. It is possible that this relates to the different conformation of the envelope in the *in vitro* adapted strains in which the lack of immune selection pressure has allowed a more open structure that favors rapid cellular entry. *In vivo*, such a structure would predispose to the blockade by neutralizing antibodies and may be disadvantageous.

Other evidence suggesting that antibodies are of relatively low importance is the fact that some individuals in whom the illness appears to be held in check by the immune response do not have high levels of neutralizing antibody. In addition, passive protection using antibodies in animal models is only effective when they are present in very high titer. There is some evidence that high titers of neutralizing antibody may be associated with a lower ''set point.'' The immense variability of the viral envelope facilitates immunological escape of the virus. This may occur either by amino acid variability or by modification of envelope glycosylation.

Cytotoxic T-cell responses can be detected before the antibody response and have long been considered one of the major immunological defenses against HIV. CD8+ T cells can kill virus infected cells by specific recognition of the HIV peptides presented on class I MHC proteins on the surface of the infected cell. *In vitro*, CTLs can eliminate infected cells even before new viruses have been produced. A second effect involves the release of β-chemokine mediators, which, as previously mentioned, are themselves able to bind to their natural ligand CCR5 and block the use of this protein by HIV for infection of the cell. The strong correlation between appearance of CD8+ T cells and the decline in viral replication in the early stages together with data on adoptive transfer in humans and CD8 depletion experiments in monkeys, which leads to a sustained increase in viral load, confirms the critical role played by this arm of the immune response in combating infection.

The signature of HIV infection is the decline in CD4 lymphocytes. The mechanisms of destruction of CD4 lymphocytes are probably many and varied as described earlier. Production of HIV with its gp120 within a cell that is already making CD4 may lead to protein aggregation within the cell and dysfunction leading to apoptosis. This can be observed *in vitro* as single cell killing. Expression of gp120 on the surface of the cell may induce fusion of that cell with a CD4+ cell. This latter phenomenon is also seen *in vitro* and leads to killing by syncitia formation. Passive binding of shed gp120 on to the CD4 proteins of immune competent cells may lead to them being a target for immunological clearance and the gp120 itself may have adverse effects. The cytotoxic T-cell response, clearing infected cells, is probably responsible for a very large proportion of the destruction of CD4+ infected cells. Thus, a number of direct and indirect mechanisms contribute to the loss of the CD4 cell population.

Individuals whose disease progresses very slowly (long-term nonprogressors – LTNPs) have clearly been shown to have powerful T-cell responses against HIV with the CD4 lymphoproliferative

response correlating well with successful suppression of the viral load. Whether these cells act independently or through enhancement of CD8+ CTL killing is not clear and it may be a combination of both. Apart from specific genetic variants such as the CCR5 truncation mutation described earlier, there does appear to be some genetic influences in that certain HLA alleles HLAB35 and CW4 are associated with more rapid disease progression, and certain other polymorphisms in chemokines and chemokine receptor genes may influence responses to therapeutic strategies and vaccination.

The immune response is capable of a measure of control of HIV replication in all patients, and in some, there is very significant delay in the onset of AIDS. Recent evidence suggests that not only does the ability to mount an immune response decline as disease progresses but the ability to regenerate this when antiretroviral treatment is started also declines the longer the initiation of treatment is delayed. Indeed, treatment during the early stages of infection at seroconversion has been correlated with a much better long-term CD4 lymphoproliferative response. Thus, early treatment might lead to the ability to maintain a strong CD4 cell response and this might provide the possibility of powerful long-term control of viral replication. Against this is the risk of generating drug resistance early in infection and the loss of utility of the limited range of chemotherapeutic agents when they may be more useful at a later stage.

6 Drug Therapy of HIV

Antiviral drugs are commonly targeted at viral enzymes. This is the case with HIV in which the first two types of highly successful pharmacotherapies have been directed to inhibit the actions of the viral reverse transcriptase gene and the protease gene. Reverse transcriptase is clearly a virus-specific process since the cell does not have any functional RNA-dependent DNA polymerase activity. The reverse transcriptase enzyme does not have proof-reading capability and while, as mentioned later, this may be an advantage to the virus in generating variants, it also is an Achilles' heel for the virus in that nucleoside analogs that mimic the bases that the enzyme is attempting to incorporate into the DNA chain can substitute for these and once inserted cannot be excised. Pyrimidine analogs have been particularly effective and they appear to act both by inhibiting the enzyme and by chain termination. They require phosphorylation within the cell to form triphosphates. Another class of drug that inhibits RT is the nonnucleoside reverse transcriptase inhibitors (NNRTIs), which bind to reverse transcriptase away from the active site but are not incorporated into the transcript. A third major class of antiretroviral drugs are those inhibiting the viral protease. These take advantage of the target peptide sequence of the aspartyl protease of HIV, being slightly different from cellular homologs of this enzyme. Predictably, however, the specificity of these drugs is somewhat lower than RT inhibitors and they are associated with a greater number of side effects, probably relating to effects on cellular proteases. Newer classes of drugs are being developed including those that may inhibit viral entry, viral integration, and viral export. Injection of a peptide, which interferes with the formation of the fusogenic envelope of the virus and blocks cell entry, has recently been introduced into clinical practice.

Structured treatment interruptions (STI) is being tested as a strategy to reduce drug toxicity. As yet, the effect of this on overall prognosis and immune regeneration is not fully established.

7 Viral Escape

The previously described infidelity of the reverse transcriptase enzyme is responsible for considerable sequence change in the virus. Undoubtedly, many of the incorporated nucleotides will cause lethal mutations and a nonviable integrated provirus will result. The huge numbers of viruses being produced everyday, however, will ensure that a large number of viable variants will be produced, which may have minor changes in their amino acid sequence. Thus, it is easy to see that a virus entering a macrophage may mutate slightly during its reverse transcription and integration process such that the progeny virions from that cell may have a slightly greater predisposition to infect lymphocytes than the parental version. The other major mechanism of sequence variation comes from recombination. When a cell is infected with two different viruses, the diploid nature of the genome means that it is possible for an RNA strand from two different integrated proviruses to be copackaged. During reverse transcription in the target cell, the reverse transcriptase enzyme is known to dissociate from its template and may reassociate with the partner template. Thus, exchange of large blocks of genetic information between the two strands is quite common. Indeed, it is estimated that the enzyme skips between strands at least four times during every replication cycle. In this way, mixing and matching of genomes can occur with ease and, in this case, large blocks of functionally intact genome will be changed. Recombination is, therefore, believed to be as significant if not more significant than RT errors in generating diversity. Some of the major worldwide clades have clearly been formed from recombination. Genotype E in Thailand, for example, is a recombinant between a clade A Gag and a clade E envelope sequence.

Variation allows the virus to introduce point mutations, which will render the binding of antiviral drugs much less efficient, and strategies to combat viral resistance have become an integral part of clinical management. This is particularly the case since antiviral therapy in the western world became more widespread. The chances of acquiring a virus, which has already generated some antiviral resistance, has increased greatly. For this reason, where possible, it is recommended that antiviral resistance testing is undertaken before initiating antiretroviral therapy so that the combination of drugs chosen is one in which the virus is sensitive to each component. As well as this, it is vital that combinations of three or more drugs are used to prevent emergence of resistance. Both of these strategies are designed to avoid presenting the virus with a single drug against which it can develop resistance.

The genetic variation also contributes very largely to the difficulty the immune system has in neutralizing this virus. There are clearly documented examples of immunological escape where viral proteins, which have cytotoxic T-cell epitopes, mutate and thus escape cytotoxic T-cell recognition. In terms of envelope variation, the virus has the additional weapon of variable glycosylation. HIV envelope is extremely heavily glycosylated compared to a number of its close viral relatives

and it is clear that glycosylation may significantly inhibit the function of neutralizing antibodies.

8 Vaccines

From the above, it is clear that the development of a vaccine against HIV is a monumental task compared to many other pathogens. The features that make it particularly challenging are as follows. Firstly, there is no evidence that complete sterilizing immunity occurs in the human race after infection. Thus, even the best immune response in the world does not appear to be capable of indefinitely checking virus replication. Secondly, the huge variability of the virus means that unlike, for example, polio or smallpox, vaccines containing a restricted number of variants will not successfully prevent infection and disease caused by HIV since the virus has such a vast repertoire of viable variants. Thirdly, the virus integrates into the genome of the cell. A number of the features of the life cycle of this and other retroviruses have been designed to specifically maintain cellular viability since death of the cell equates with death of the provirus. The action of many of the accessory genes of HIV in downmodulating cell surface proteins makes even a good immune response incapable of easily clearing infection. Over and above that, however, the virus has the capacity to become latent. Complete transcriptional arrest may occur (or a level of basal transcription insufficient to generate Tat), with transcriptional reactivation occurring under appropriate conditions such as triggering of the cell into mitosis. A transcriptionally inactive virus is completely invisible to the immune system and persistence of a small number of latently infected cells leaves the possibility of reactivation when the immune response wanes. Reactivation of other viruses such as *Varicella zoster* provides a comparable parallel. It is, thus, not surprising that progress toward a vaccine has been slow. To date, vaccines have been generated that are capable of preventing infection in SIV models. Most of these appear to be effective against homologous strains but with, as yet, relatively little evidence that effective cross-neutralization of heterologous strains occurs. Use of a live attenuated vaccine such as one deleted in *nef* and some of the other regulatory genes has been associated with protection against subsequent challenge. Attenuation, however, appears to be a finite phenomenon and mutation back to the wild-type sequence and full pathogenicity is a feature. Recent data using prime boost techniques in which carrier vaccine strains are used such as modified vaccinia Ankara have shown some promising evidence of good immune responses against HIV proteins. As yet, the duration of immune response using these techniques is not clear. A cohort of prostitutes in western Africa who were repeatedly exposed to HIV but remained uninfected originally, generated hope that a fully neutralizing immune response was possible with frequent low level viral challenge. The follow-up of these individuals showed that when sexual exposure to HIV ceases, the immunity wanes and the individuals become susceptible to infection again. This, again, is rather a concerning issue in terms of vaccine development since it would suggest that repeated boosts of vaccination will be required to maintain a level of immunity, which would otherwise be lost. There are strong parallels here with immunity to malaria.

9 Summary

The HIV epidemic is a global problem that has been controlled but not eliminated in the western world. The vast majority of infected individuals live in sub-Saharan Africa where access to treatment for the virus or its complications is extremely limited. Significant loss of life and disruption of family and society has occurred in this part of the world due to HIV. Recurrent suggestions that HIV may not be the causative agent of AIDS have seriously set back educational programs in a number of countries and are unfounded and irresponsible. Countries that have taken advice and help and approached the problem with a vigorous education campaign such as Uganda have reaped the rewards with the HIV positivity rate in the antenatal population halving over a period of less than 10 years. Until vaccines are developed and antiretroviral therapy becomes more widely available, these sort of approaches should be powerfully supported. In the western world, antiretroviral therapy has transformed the prognosis, and conceivably, a middle aged person acquiring HIV might now have a normal lifespan given the additive effects of the slow onset of clinical disease, the availability of antiretroviral drugs, and the combined time window these provide for the appearance of new therapies. While the death rate has fallen in the west, the incidence of HIV infection has continued to rise. This is partly because of increased longevity of infected individuals and also from increasing numbers of migrants from highly endemic areas who may seek access to western health resources. This trend is increasing and will provide an increasing burden on western healthcare services. There is still no reason why an uninfected person cannot be protected against HIV since transmission is preventable by barrier methods of contraception, vaginal virucidal agents, and so on. However, the key to the control of HIV in the near future in the developing and developed world is education.

Keywords

Pre-mRNA
Nascent transcripts that are precursors of mature messenger RNAs.

Exon
Gene regions that are present in mature messenger RNA transcripts.

Intron
Intervening sequences that are removed from pre-mRNA transcripts and not represented in mature mRNA species.

Pre-mRNA Splicing
The process of removing introns from pre-mRNAs and ligating exons to form mature mRNA transcripts.

UsnRNPs
Uridine-rich small nuclear ribonucleoprotein particles.

Spliceosome
The macromolecular machine in which pre-mRNA splicing reactions take place.

5′ and 3′ Splice Sites
Sequences that spliceosomes recognize at 5′ and 3′ ends of an intron. They are also named splice donor and splice acceptor sites respectively.

Alternative Splicing
The process in which cells selectively use different combinations of splice sites to generate two or more mRNA transcripts from a single pre-mRNA species.

Splicing Regulatory Elements
Specific sequences in introns or exons that are recognized by trans-acting factors to allow either enhancement or repression of splicing.

Splicing Regulators
Trans-acting factors that interact with splicing regulatory elements to either stimulate or inhibit splicing.

An important step of eukaryotic gene expression is pre-mRNA splicing, the process of removing intervening sequences (introns) from the nascent transcript (messenger RNA precursor, or pre-mRNA). The discovery of split genes in the viral genome and subsequent research in the field of pre-mRNA splicing have greatly advanced our understanding of mammalian gene regulation. Studies on pre-mRNA splicing have also facilitated sequence analyses of the human genome. With the completion of human genome sequencing, it is now further appreciated that pre-mRNA splicing and alternative splicing play critical roles in regulating gene expression and in enhancing genetic diversity.

Evolutionarily, the basic machinery for pre-mRNA splicing appears to be highly conserved among different species of metazoans. In *Saccharomyces cerevisiae*, although only a small percentage of genes undergo splicing, more than 100 genes have been identified that are either dedicated to or involved in pre-mRNA splicing. In mammals, pre-mRNA splicing is a crucial step for gene expression because the vast majority of mammalian transcription units contain one or more introns that must be accurately removed to form mature and functional messenger RNA (mRNA) species. In this chapter, we review the current knowledge about mammalian pre-mRNA splicing, with special emphasis on the aspects related to the pathogenesis or treatment of human diseases.

1 Pre-mRNA Splicing and Splicing Machinery

1.1 Splicing Machinery: Spliceosome

Pre-mRNA splicing is the first step of the major post-transcriptional processes in eukaryotic gene expression (Fig. 1). The biochemical reactions of pre-mRNA splicing occur in a macromolecular machine named the *spliceosome*. This large RNA–protein complex contains, in addition to the pre-mRNA substrate, several uridine-rich small nuclear ribonucleoprotein (UsnRNP) particles as well as a myriad of non-snRNP protein factors. The splicing machinery is similar in complexity and size to that of the protein synthesis machinery, the ribosome. In all cases studied so far, splicing reactions take place in the mature spliceosome inside the nucleus.

For processing the majority of introns (the major class, also called the U2-type

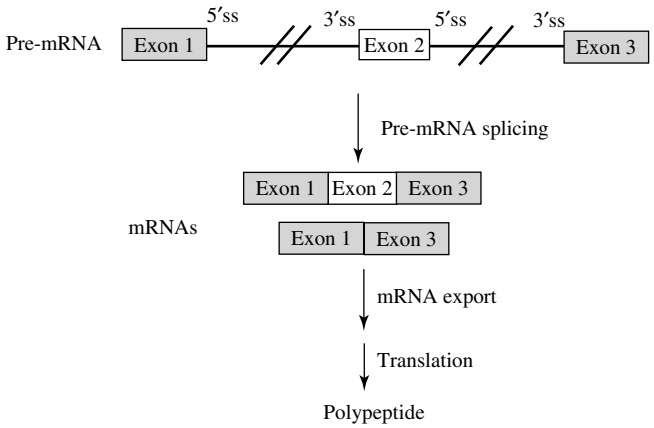

Fig. 1 The schematics for major posttranscriptional processes in eukaryotic gene expression. Different splice isoforms of mRNAs can be produced as a result of alternative selection of splice sites.

intron), the spliceosome contains U1, U2, U4/6, and U5snRNPs. The splicing of the minor class of introns (also called the U12-type) occurs in the spliceosome containing U11 and U12, in addition to U4atac, U6atac, and U5snRNPs (Figs. 2 and 3). This chapter will focus on the splicing of introns in the major class. This is because this class accounts for more than 99% of known introns. Most of our knowledge about pre-mRNA splicing has also come from studies of the major class of introns.

Comparison of genes coding for components of splicing machinery, including both snRNAs and protein factors, reveals a high degree of conservation through evolution. Amazing similarity is found among spliceosomal components from yeast, fruit fly, and human. A recent study using nanoscale microcapillary liquid chromatography tandem mass spectrometry to analyze partially purified human spliceosomes assembled on model splicing substrates revealed 145 distinct spliceosomal proteins. This suggests that the spliceosome is one of the most complex macromolecular machines for mammalian gene expression. Table 1 shows the currently known human proteins identified in functional spliceosomes assembled on model splicing substrates. The role of individual proteins in splicesome assembly and in splicing regulation will be discussed.

1.2 Splicing Signals

The sites for cleavage and ligation in splicing reactions are defined by conserved splicing signals in the pre-mRNA, including the 5′ splice site (5′ss), the branch site, the polypyrimidine tract, and the 3′ splice site (3′ss) consensus sequence. These cis-elements are important sites for RNA–RNA and protein–RNA interactions. Systematic analyses of both yeast and higher eukaryotic splicing signal sequences led to the classification of U2 and U12 types of introns based on the key UsnRNPs involved in the recognition of the branch sites in the corresponding introns (Fig. 2).

In general, the spliceosome for U2-type introns contains U1, U2, and U4/U6,

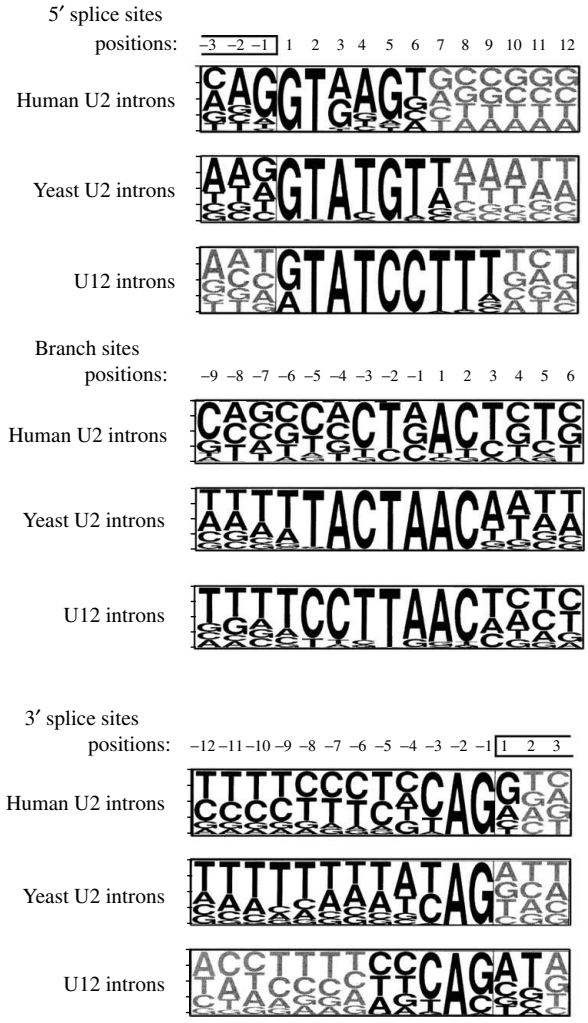

Fig. 2 The sequence features at the 5′ splice site, branch site, and 3′ splice site as derived from representative sets of introns of corresponding types. (Modified with permission from Burge, C.B., Tuschl, T.H., Sharp, P.A. (1999). in: The RNA World, Gesteland, R.F., Cech, T.R., Atkins, J.F. (Eds) *The RNA World*, Cold Spring Harbor Laboratory Press, New York, pp. 525–560). The frequency of each nucleotide (A, G, T, or C) at each sequence position is depicted by the heights of the corresponding letters in the diagram.

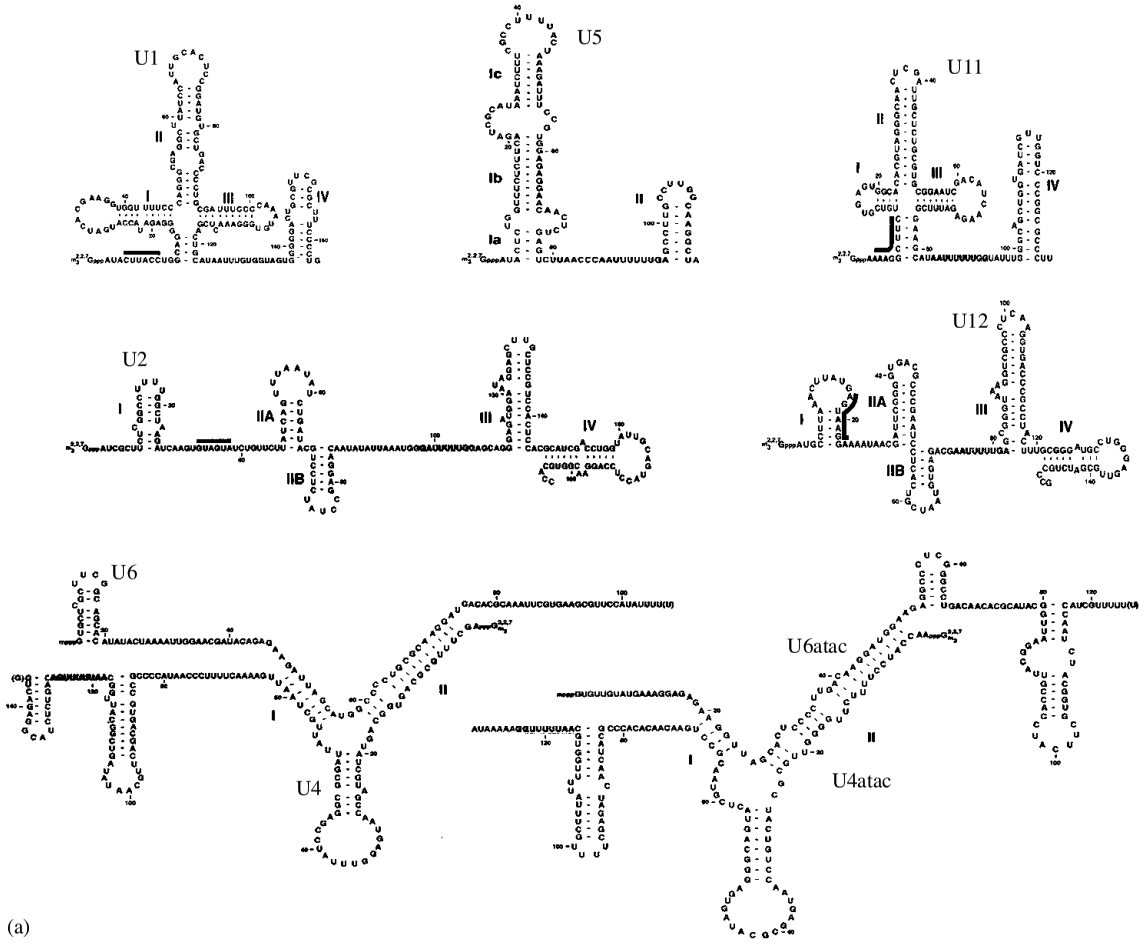
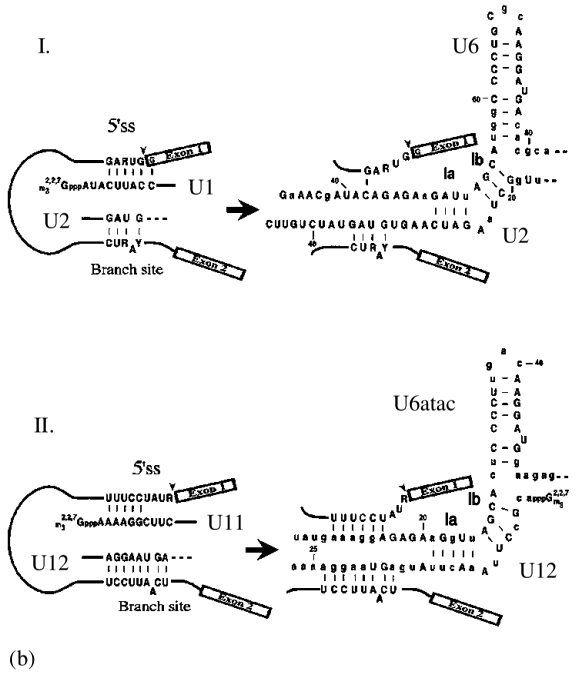


(a)



(b)

Fig. 3 Sequences of human spliceosomal UsnRNAs and their interactions with splice sites. Panel (a) Sequences and secondary structures of spliceosomal snRNAs: U1, U2, U4/6 (for the U2 type), and U11, U12, U4atac/U6atac snRNA (for the U12 type) as well as U5snRNAs (for both classes). The 5′ to 3′ orientation of U4 and U4atac is from right to left, and that of U1, U11, U2, U12, and U5snRNAs is from left to right. The RNA helices are indicated by Roman numerals, and nucleotide positions by Arabic numerals. The shaded nucleotides are binding sites for Sm proteins, and regions marked with black lines form base-pairing interactions with the pre-mRNA. (Modified with permission from Burge, C.B., Tuschl, T.H., Sharp, P.A. (1999). in: The RNA World, Gesteland, R.F., Cech, T.R., Atkins, J.F. (Eds) *The RNA World*, Cold Spring Harbor Laboratory Press, New York, pp. 525–560.) Panel (b) Base-pairing interactions in the U2 and U12 types of spliceosome. The exon-intron boundaries at 5′ splice sites are marked by arrowheads. During early stages of spliceosome assembly, U1 or U11snRNP interacts with the 5′ splice site, and U2 or U12snRNP with the branch sites. These interactions are displaced in mature spliceosome by U6 or U6atac associated with U2 and U12 respectively. In these drawings, the distances between interacting nucleotides do not reflect corresponding physical distances in the spliceosome. (Adapted from Tarn, W.Y., Steitz, J.A. (1996b) Highly diverged U4 and U6 small nuclear RNAs required for splicing rare AT-AC introns, *Science* **273**(5283), 1824–1832.)

Note: A. snRNP proteins. B. Non-snRNP spliceosomal proteins. C. Late-acting spliceosomal proteins. In each list, spliceosomal proteins are grouped by their structural motifs. Corresponding GenBank accession numbers are shown (Acce#), together with their yeast homologs (as SGD open reading frame, SGD ORF), sequence motifs, and calculated molecular weight (Cal. Mwt).
COLD: cold shock RNA-binding domain; Cyclophilin: cyclophilin type peptidyl–prolyl cis–trans isomerase; DEATH: domain found in proteins involved in cell death; DExD: DExD/H-like helicases superfamily; DSRM: double-stranded RNA-binding motif; ERM: ezrin/radixin/moesin family motif; fSAP: functional spliceosome-associated protein; FF: two conserved F residues; G domain: GTP-binding domain that contains a P-loop motif; GYF: contains conserved G-T-F residues; HAT: Half-A-TPR (tetratrico-peptide repeat); Gly-rich: peptide sequences rich in G, R, S residues; HELICc: helicase superfamily c-terminal domain; KH: hnRNP K homology RNA-binding domain; MIF4G: middle domain of eukaryotic initiation factor 4G; NOP: putative snoRNA binding domain; NUDIX: mutT-like domain; PABP: poly-adenylate binding protein, unique domain; PP2A: protein phosphatase 2A repeat; PWI: domain in splicing factors; RED: protein with extensive stretch of alternating R and E or D; RRM: RNA recognition motif; RS: arginine–serine-rich domains; SKIP: conserved domain found in chromatinic proteins; Sm: snRNP Sm proteins; SWAP: suppressor-of-white-apricot splicing regulator; TUDOR: a domain present in several RNA-binding proteins; TyrKc: tyrosine kinase, catalytic domain; UBQ: ubiquitin homologs; Ubox: modified RING finger domain; WD40s: WD40 repeats, structural repeats of the beta propeller domain; WW: domain with 2 conserved W residues, interacting with proline-rich polypeptides; ZF: Zinc finger domain.

whereas the U12-type of spliceosome involves U11, U12, and U4atac/U6atac, with both sharing U5snRNP. Although nucleotide sequences of U11, U12, and U4atac/U6atac snRNAs are different from their counterparts in the spliceosomes for U2-type introns, the predicted secondary structures of the corresponding snRNAs have striking similarity (Fig. 3a). In addition, the specific interactions between the spliceosomal snRNAs and pre-mRNA substrates also appear to be highly similar, as shown in Fig. 3(b). Both U2- and U12-types of introns can be found in the same genes. There is evidence suggesting that the two types of spliceosomes may interact and share some protein components in addition to the common U5snRNP. The evolutionary origins of these two types of spliceosomes remain largely speculative.

U12-class introns contain more conserved sequences at the 5′ss. The sequences around branch sites of the U12-class introns are also highly conserved with the TCCTTAAC (the underlined A as the branch site) consensus signal located approximately 10 to 20 nucleotides upstream

of the 3′ss. A typical U12-class intron lacks a polypyrimidine tract between the branch site and the 3′ss.

In the yeast, *S. cerevisiae*, only a small fraction of genes contain introns, and these are usually short introns (approximately 240 introns, averaging 270 nucleotides in length). Splicing signals in yeast introns are highly conserved and may contain sufficient information for defining splice junctions, especially considering the number of genes devoted to or associated with pre-mRNA splicing in the yeast genome.

In mammals, pre-mRNA transcripts are usually much longer and contain multiple introns of variable sizes. In humans, the average size of exons is 150 nucleotides, and that of introns is approximately 3500 nucleotides. Mammalian introns can be as large as 500 kbp. The basic splicing signals in mammalian pre-mRNAs are degenerate, especially in the case of U2-type of introns. The branch sites for U2-type introns are highly divergent. At both the 5′ss and 3′ss, only two nucleotides (/GT at the 5′ss and AG/ at 3′ss) are highly conserved. As a result, the nucleotide sequences surrounding the splice junctions, the 5′ss and 3′ss, usually contain only a limited amount of information. This is not sufficient for conferring the specificity required to achieve accurate splice site selection. In mammals, the recognition of not only exon–intron junction sequences but also the regulatory elements in intronic and exonic regions is important for defining splice junctions and maintaining splicing fidelity. In addition, multiple networks of interactions among the machineries for transcription, cap formation, splicing, and polyadenylation may also influence splice site selection. This high degree of degeneracy in the splicing signals in mammalian pre-mRNA transcripts provides the flexibility for alternative selection and pairing of different splice sites, a fundamental mechanism for regulating alternative splicing.

1.3 Spliceosomal UsnRNP Biogenesis

As essential subunits of the splicing machinery, spliceosomal UsnRNPs contain not only uridine-rich snRNAs but also a number of polypeptides. U1, U2, U4, and U5snRNAs are transcribed by RNA polymerase II as precursors containing additional 3′ nucleotides. After acquiring a monomethylated guanosine (m7G) cap structure, these pre-UsnRNAs are exported to the cytoplasm in a pathway dependent on the m7G cap, the cap-binding complex (CBC), RanGTP, and phosphorylated adaptor for RNA export. In the cytoplasm, pre-UsnRNAs interact with Sm proteins including B/B′, D3, D2, D1, E, F, and G (Table 1A) to form the snRNP core structure.

The Sm protein-binding sites in U1, U2, U4, and U5snRNAs are highly conserved, containing two stem-loop structures flanking PuAU4-6GPu sequence (Fig. 3a). A number of proteins interacting with Sm proteins have been identified, including the protein product of SMN (survival of motor neuron) gene, SMN-interacting protein/Gemin2, Gemin3, and Gemin4. Genetic defects in the SMN gene cause spinal muscular atrophy (SMA), possibly by interfering with UsnRNP Sm core assembly and therefore deficiency in UsnRNP biogenesis.

Following UsnRNP Sm core assembly, the m7G cap of their snRNA is converted to the 2,2,7-tri-methylated guanosine (m3G), and the 3′ extra nucleotides of pre-UsnRNAs are removed. These core UsnRNPs are imported into the nucleus to

be assembled into the spliceosome. This UsnRNP import process requires not only general nuclear import factors such as Importin-β but also specific factors such as Snurportin-1 that recognizes the m3G cap of the UsnRNP and interacts with general factors for snRNP import into the nucleus.

Before the association of UsnRNP particle-specific proteins, the UsnRNAs undergo internal modifications including pseudouridylation and 2′-O-methylation. Such modifications appear to be necessary for the assembly of a functional UsnRNP, as shown for the human U2snRNP. These posttranscriptional modifications are mediated by a small nucleolar (sno)RNA-guided mechanism through the action of snoRNPs. For example, U85 snoRNP directs both 2′-O-methylation and pseudouridylation of U5snRNA. Following these posttranscriptional internal modifications of snRNAs, the assembly of UsnRNPs is completed with the association with individual UsnRNP-specific proteins (Table 1A). Among these UsnRNP-specific proteins, U5-220 kDa (also named Prp8 or PRPC8) is a crucial spliceosomal protein that is most highly conserved through evolution. Prp8 interacts with sequences of all major splicing signals including 5′ss, branch site, and 3′ss. It has been proposed that Prp8 plays a critical role in catalysis by aligning 5′ss, and 3′ss at the catalytic center.

U6snRNP plays an important role at the catalytic center of the spliceosome, and its biogenesis has several unique features. The U6snRNA is transcribed by RNA polymerase III, and its cap structure is a γ-monomethyl group. The U6snRNP does not contain an Sm protein. Instead, U6snRNP contains seven Sm-like proteins (Lsm2, 3, 4, 5, 6, 7, and 8) interacting with the U-rich region at the 3′ end of the U6snRNA. The assembly of U6snRNP is believed to occur in the nucleus. The base-pairing interactions between U4snRNA and U6snRNA lead to the formation of the U4/U6snRNP, which associates with U5snRNP as the U4/U6.U5 tri-snRNP complex to join the spliceosome. The formation of U4/U6.U5 tri-snRNP complex and association of tri-snRNP with the spliceosome require PRPF31 (human homolog of yeast Prp31p) in addition to other proteins.

1.4 Spliceosome Assembly

A large number of studies show that mammalian spliceosomes are assembled on the pre-mRNA splicing substrate in an orderly fashion. A recent study, on the other hand, reported a penta-snRNP particle purified from the yeast extract. The finding of this ''preassembled'' penta-snRNP particle suggests the potential importance of concurrent multisite interactions during spliceosome assembly among spliceosomal components and different intronic as well as exonic regions. Many components of spliceosomes are conserved between yeast and human. In fact, much of our knowledge of spliceosome assembly is based on genetic studies in yeast and on biochemical experiments using both yeast and mammalian systems. The mammalian homologs of key spliceosomal components have been identified (Table 1). Systematic proteomic studies of spliceosomes assembled on model splicing substrates confirm the high degree of conservation between mammalian and yeast spliceosomal proteins (Table 1).

Spliceosome assembly is a highly dynamic process, with multiple RNA–RNA, RNA–protein, and protein–protein interactions. During spliceosomal assembly

and activation, there are a series of conformational rearrangements. This process involves not only changes in the RNA conformation but also remodeling of snRNPs and exchanges of protein factors. Studies over the past two decades have only provided a sketch of this multicomponent interactive process. At the catalytic center of the functionally mature spliceosome, the 5′ss and 3′ss must be juxtaposed precisely to ensure accurate cleavage and ligation.

The classical view of spliceosome assembly features stepwise interactions between the pre-mRNA substrate and different spliceosomal UsnRNPs. Immediately after transcription, nascent pre-mRNA transcripts interact with hnRNP (heterogeneous nuclear ribonucleoprotein) proteins (Table 2) to form *H complex*. Spliceosome assembly is initiated with the recognition of the 5′ splice site by U1snRNP in an ATP-independent manner. Efficient interaction between the U1snRNP and 5′ splice site requires U1snRNP-specific proteins (such as U-70 K) and possibly other proteins. Recognition of the branch site and 3′ splice site requires cooperative binding of SF1 (also named the *branch point binding protein*, BBP) to the branch site and binding of U2 auxiliary factor (U2AF65 and U2AF35 as a

The H complex proteins that are involved in alternative splicing regulation are marked with ''**.''

heterodimer) to the intronic sequence at the 3′ splice site. Splicing reactions can occur in the absence of detectable U1snRNP. However, efficient splicing of most introns appears to require U1snRNP. The formation of such an early complex (*E complex*) is considered to be the commitment step that directs the nascent pre-mRNA transcript into the splicing pathway.

A distinct feature of the formation of mammalian splicing commitment complex is the involvement of a family of proteins named SR proteins that are not found in the genome of *S. cerevisiae*. SR proteins share common structural features, with one or two RNA recognition motifs (RRMs) of the RNP-consensus (RNP-cs) type at the amino-terminus and a carboxyl domain rich in arginine and serine residues (RS domain, Table 1). These proteins play important roles in recognizing exons and mediating interactions between splice sites. SR proteins interact with exonic sequences and recruit splicing factors for the formation of ''cross-exon'' complex, (i.e. exon definition). SR proteins also interact with 5′ss and facilitate the ''cross-intron'' recognition by mediating protein–protein interactions between U1snRNP and factors associated with the branch site 3′ss including U2snRNP, U2AF, and possibly other proteins.

The binding of U1snRNP and SR proteins promotes the interaction of the 17S U2snRNP with the branch site sequence. The stable association of U2snRNP with the branch site to form the *A complex* is ATP-dependent and requires the U2snRNP-specific proteins SF3a [SF3a60/SAP61 (Prp9), SF3a66/SAP62 (Prp11) and SF3a120/SAP114 (Prp21)]. This process also requires non-snRNP splicing factors including hPrp5 (a putative ATP-dependent RNA helicase). Upon the integration of the U2snRNP complex, a U2snRNP-protein, p14, contacts the branch adenosine residue and interacts with other U2snRNP proteins. The next ATP-dependent step is the association of U4/U6.U5 tri-snRNP complex to form the *B1 complex*, in which the interaction of the 5′ss with U1snRNA is destabilized by U5-100 kDa (hPrp28), a putative RNA helicase. The 5′ss sequence is then engaged in interactions with U6snRNA around the intronic region and with U5snRNA at the exonic region. After escorting the U6snRNP into the B1 complex, the U4snRNP is released to form the *B2 complex*, a transition that requires ATP and possibly U5-200 kDa (human homolog of Brr2 in yeast, another putative RNA helicase). The next ATP-dependent transition is the formation of the *C1 complex*, a process involving the activity of yet another possible RNA helicase hPrp2 (human homolog of Prp2/Ynr011c). This may directly lead to the formation of the catalytic site for the *first step of splicing*, the cleavage at the 5′ss with the formation of a lariat intermediate (see Fig. 4). U2, U6, and U5snRNPs are associated with the catalytically active form of splicing complex in which the first step of splicing occurs. The *second step of splicing* (cleavage at the 3′ss and ligation of exons) requires an additional set of protein factors including hPrp16, hPrp17, hPrp18, and hSlu7 (Table 1). The human homolog of the yeast Prp16, hPrp16, contains an RS domain in addition to DEXD-box helicase and ATPase domains. The transition to form the *C2 complex* is again ATP-dependent. The catalytic center for the second step is also formed by U6snRNA, U2snRNA, and/or associated proteins. The splicing products, ligated exons, and the lariat intron, are then released from the spliceosome by

another DEXD-box containing RNA helicase together with other factors. The release of the lariat intron and dissociation of U2, U5, and U6snRNPs from the *I complex* requires another putative RNA helicase, hPrp43. The released U6snRNP is reannealed with U4snRNP and associated with U5snRNP to form the U4/U6.U5 tri-snRNP complex to enter another cycle of spliceosome assembly. The lariat intron is debranched by the enzyme Dbr1. Many spliceosomal components are presumably recycled to form new spliceosomes.

It is clear that spliceosome assembly is a highly dynamic process involving multiple networks of RNA–RNA, protein–RNA, and protein–protein interactions at each step. Our understanding of this complex process, as well as its regulation, remains limited.

1.5 Biochemical Mechanisms of pre-mRNA Splicing

The complex and dynamic process of spliceosome assembly culminates in the formation of the catalytic core in which 5′ss and 3′ss are precisely juxtaposed. The biochemical reactions of pre-mRNA splicing involve two transesterification steps (Fig. 4). The first step is the cleavage at the 5′ss and the formation of the lariat intermediate with a 2′-OH displacing a 3′-OH group. The second step is the cleavage at the 3′ splice site with concomitant ligation of the 5′ and 3′ exons in which a 3′-OH displaces another 3′-OH group. Although it remains controversial, these two steps of splicing reactions may take place in two catalytic sites. In addition to the chemical differences between the

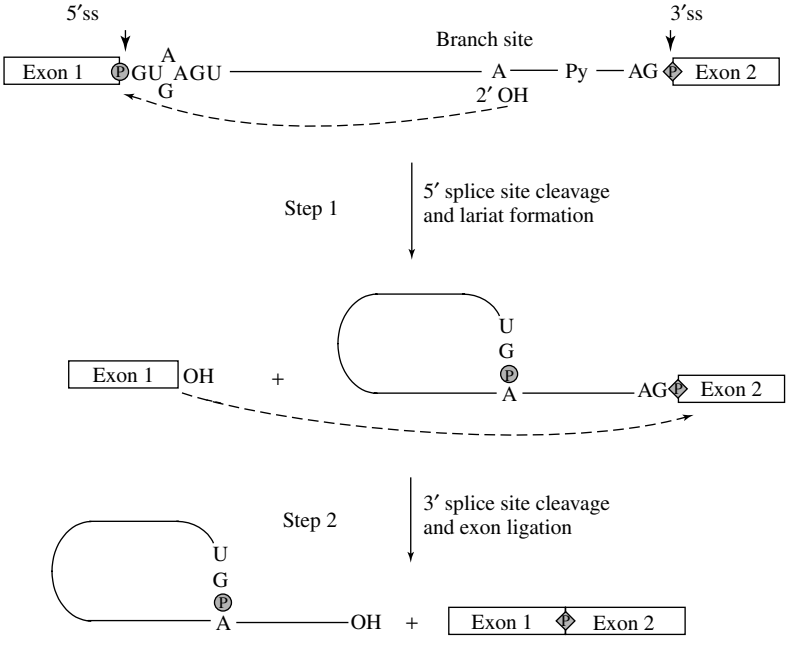

Fig. 4 The biochemical mechanisms of pre-mRNA splicing: two steps of transesterification. The phosphodiester linkages are indicated by the letter "p" inside a circle or a diamond.

two reaction steps, the stereoselectivity of the transesterification reactions and the difference in the metal-ion dependence support the existence of two reaction sites.

Accumulating evidence suggests that pre-mRNA splicing may be RNA-catalyzed with U6snRNA at the center for catalysis and protein factors including PRP8 as components of the catalytic core. U6snRNA plays a critical role in catalysis and in interacting with pre-mRNA and other spliceosomal snRNAs. In yeast, U6snRNA contributes to spliceosomal catalysis by coordinating catalytic metals. Precise catalytic mechanisms of mammalian pre-mRNA splicing remain to be elucidated.

2
Alternative pre-mRNA Splicing

2.1
Alternative Splicing and its Role in Regulating Gene Activities and Generating Genetic Diversity

The vast majority of vertebrate genes contains at least one intron. It is estimated that more than 50% of human genes undergo *alternative splicing*, the process that generates distinct splicing products from the same pre-mRNA transcript by using different splice sites (Fig. 5). Alternative splicing is an important mechanism for regulating gene activities in eukaryotic species. Alternative splicing events can

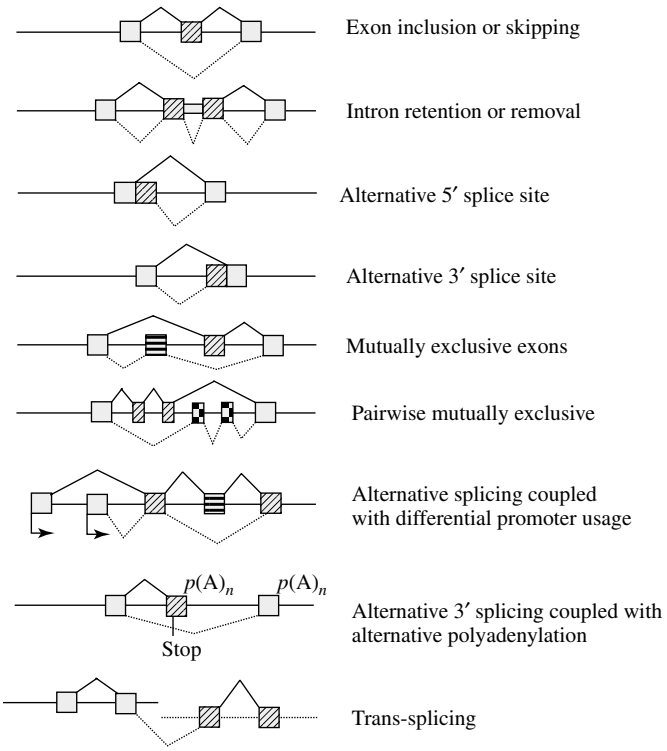

Fig. 5 Diverse patterns of alternative splicing. Alternatively spliced regions or exons are illustrated as shaded boxes.

occur in the protein-coding regions or in the regulatory regions of genes, including both 5′ and 3′ untranslated regions. Alternative splicing can affect peptide coding capacity or influence mRNA stability or translational control of the transcription products. Alternative splicing regulation can also be coupled with transcription, polyadenylation, RNA editing, or mRNA exporting processes. A recent example for the coupling of splicing with other processes of gene regulation is that steroid hormone receptors can simultaneously regulate transcription and alternative splicing by recruiting coregulators involved in both processes. In addition, alternative splicing can affect posttranslational modifications of protein products.

2.1.1 Different Patterns of Alternative Splicing

A number of distinct alternative splicing patterns have been reported (Fig. 5). Most common alternative splicing events include exon inclusion/skipping, intron removal/retention, and alternative selection of competing 5′ or 3′ splice sites. More complex patterns of alternative splicing include mutually exclusive or cassette types of exon inclusion. Alternative selection of terminal exons can be coupled with differential promoter usage or polyadenylation. Furthermore, recent studies have documented possible alternative trans-splicing of mammalian genes, although it may occur only at a low frequency in mammals.

2.1.2 Alternative Splicing and Genetic Diversity

Alternative splicing regulates gene activities involved in every aspect of cell survival and function. It is a major mechanism for generating the complexity of mammalian proteomes. Alternative splicing contributes to proteome expansion by a number of mechanisms, such as the usage of distinct translation start sites, in-frame nucleotide deletion or insertion, changes in peptide sequence, and alternative usage of different translation stop codons. Such changes in peptide sequence or length may lead to the formation of proteins with distinct properties, including biochemical/biophysical characteristics, subcellular localization (secreted versus membrane associated, membrane-tethered versus cytoplasmic, cytoplasmic versus nuclear), posttranslational modifications (glycosylation, phosphorylation, or lipid modification), or interactions with other cellular components.

Alternative splicing can be an excellent mechanism for generating functionally antagonistic products from the same genetic locus and for the fine-tuning of gene activities at the posttranscriptional level. For example, alternative splicing of a number of genes critical for cell death leads to the formation of both cell death–promoting and cell death–preventing splicing isoforms. These include genes encoding for death ligands, death receptors, Bcl-2 superfamily of death regulators, caspases, and other cell-death regulatory genes. Several human caspase genes utilize alternative splicing to produce protein products that either contain or lack their enzyme active sites, resulting in antagonistic activities in cell death.

The nervous system is a good example where alternative splicing is utilized to generate extreme functional diversity. A vast number of genes involved in neural development and function undergo complex alternative splicing. Some genes encoding neural receptors and axon guidance molecules can generate hundreds to

even thousands of different splicing isoforms. Many ion channels and neurotransmitter receptors have different alternative splicing isoforms with distinct electrophysiological properties. Alternative splicing regulation has a significant impact on the proper function of the nervous system, including learning, memory, and behavior development.

2.2 Mechanisms Underlying Alternative Splicing Regulation

The fundamental mechanisms underlying alternative splicing are the intricate interactions among trans-acting splicing factors and cis-elements in the pre-mRNA substrates, leading to selection of different splice sites. These cis-elements include splice sites and splicing regulatory sequences (splicing enhancers or silencers). The sizes of the exons or introns, as well as secondary structures of the pre-mRNA also influence splice site selection. The highly degenerate nature of mammalian splicing signals and the existence of large numbers of trans-acting factors allow versatile RNA–protein and RNA–RNA interactions during different stages of spliceosome assembly. Such interactions can be modulated by both exonic and intronic regulatory elements. The recognition of splice sites and cis-acting splicing regulatory sequences is mediated by a network of interactions between pre-mRNA and trans-acting factors including snRNPs and non-snRNP splicing factors. A number of splicing regulators, both positive and negative, play important roles in alternative splicing regulation (Table 3). The final outcome of alternative splicing of a given gene, including the production and the delicate balance of distinct isoforms,

is determined by combinatorial effects of multisite interactions among pre-mRNA, essential spliceosomal components, and regulatory factors.

Genetic and biochemical studies in *Drosophila* genes have tremendously advanced our understanding of alternative splicing regulatory mechanisms, although some mechanisms may not be conserved in corresponding mammalian systems. For example, *Drosophila* sex determination genes are under extensive regulation by alternative splicing, and this regulatory mechanism is not conserved in mammalian sex determination. In general, *Drosophila* genes contain more small introns than mammalian genes. Here, we focus on mammalian alternative splicing regulation.

2.2.1 Splicing Signals and Splicing Regulatory Elements

Unlike the yeast spliceosome, mammalian spliceosomes have the daunting task

of searching for small exons in the vast sea of introns. This process of "exon recognition" or "exon definition" is particularly remarkable because sequences at mammalian splice sites are so highly degenerate (see Fig. 2). A large number of sequence elements with similarity to authentic splice sites (pseudosplice sites) can be found in both intronic and exonic regions). Further complicating the issue, some of these elements act as *cryptic splice sites* that are only used by the splicing machinery when the authentic splice sites are altered by mutations. Therefore, specific recognition of authentic splice sites and correct pairing of corresponding 5′ and 3′ splice sites is a central issue for both constitutive splicing and alternative splicing regulation. The intrinsic sequence degeneracy of mammalian splice sites determines that alternative splicing is a rule rather than an exception during mammalian gene expression.

In addition to splice sites, sequence elements in both intronic and exonic regions modulate alternative splicing. Such regulatory elements can either enhance or suppress splicing, and are hence named exonic splicing enhancers (ESEs) and intronic splicing enhancers (ISEs), or exonic splicing silencers (ESSs) and intronic splicing silencers (ISSs).

A number of ESE motifs have been identified using biochemical systematic evolution of ligands by exponential enrichment (SELEX) or bioinformatical approaches. A/G-rich (also called purine-rich) and A/C-rich elements are among ESE motifs characterized by biochemical studies. Proteins containing SR domains play a major role in recognizing A/G-rich ESEs and recruiting other spliceosomal components (including snRNPs and other protein factors), thereby promoting the usage of neighboring splice sites. A cold-box protein, YB-1, has been shown to enhance splicing by interacting with an A/C-rich ESE. Another ESE in HIV-1 tev-specific exon interacts with hnNRP H and SR protein SC35 to enhance splicing. The SELEX method has been used to identify preferred binding sequences for individual SR proteins, and optimal binding sites for individual SR proteins are degenerate. ESE prediction programs based on SELEX and computational analysis of human genes have been developed (http://exon.cshl.org/ESE). These programs are useful in predicting alternative splicing patterns of natural pre-mRNA substrates in cells.

ISE elements have been studied in a number of genes, including c-src, β-tropomyosin, calcitonin/calcitonin gene-related peptide gene (CGRP), fibronectin, nonmuscle myosin heavy chain, cardiac troponin T (cTNT), FGFR-2, $\alpha 2$ subunit of glycine receptor, and other genes. Such ISEs may contain sequences similar to 5′ splice site, U-rich element adjacent to the regulated 5′ splice site, UGCAUG element, (UCAUY)3-containing sequences, or CUG-containing motif.

A number of ESSs have been characterized in different genes such as β-tropomyosin, CD44, and viral genes including HIV Tat, bovine papillomavirus type-1, and Rous sarcoma virus. They do not share any obvious sequence motifs. Their activities are often associated with interactions with proteins of the hnRNP family, including hnRNPA1, hnRNP H, and hnRNP F.

A variety of ISSs have been analyzed in alternatively spliced genes including hnRNP A1, fibroblast growth factor receptor 2 (FGFR2), caspase 2, $GABA_AR\gamma 2$ (γ-aminobutyric acid receptor typeA $\gamma 2$subunit), NMDA R1 (*N*-methyl-D-aspartate receptor R1 subunit;), clathrin light chain B, and HIV tat. Many of

these ISSs contain extended polypyrimidine tracts. Some splicing repressor elements contain sequences similar to authentic splice sites, or decoy splice sites. It has been proposed that such decoy splice sites mediate nonproductive interactions to suppress the usage of upstream 5′ splice site. Again, several hnRNP proteins, including polypyrimidine tract binding protein (PTB, also known as hnRNP I), hnRNP A1, and hnRNP H play important roles in splicing repression by ISSs.

One of the common features of these cis-regulatory elements is that they are not simple sequence elements that act independently of each other. Sequence elements have been identified that can act to stimulate the splicing of one exon but repress another exon (e.g. in FGFR2 gene). Some regulatory elements contain both enhancer and silencer domains. The splicing of IgM exons M1 and M2 is regulated by a sequence containing juxtaposed splicing enhancer and silencer elements. Alternative splicing of protein 4.1R pre-mRNA generates multiple isoforms. This alternative splicing event is critical for red blood cell membrane biogenesis during erythroid differentiation and is regulated by multiple cis-elements and trans-acting regulators.

Splicing regulatory elements usually contain multiple binding sites for splicing regulators and function by recruiting other spliceosomal components to form RNP-like complexes. An evolutionarily conserved 100 bp intronic suppressor element in the caspase 2 (casp-2) gene, In100, specifically inhibits its exon 9 splicing. Alternative splicing of this 61 bp exon 9 leads to the formation of two functionally antagonistic products, casp-2L and casp-2S. Casp-2L product promotes cell death, whereas casp-2S prevents cell death. The In100 element contains a decoy 3′ splice site juxtaposed to a PTB-binding domain, both of which contribute to the full activity of In100 in inhibiting exon 9 inclusion. The upstream portion of In100 contains a sequence with features of an authentic 3′ splice site (including a branch site, a polypyrimidine tract, and AG dinucleotide). However, this site is not used under normal conditions. This sequence is only recognized as a 3′ss when the site is isolated with the downstream PTB-binding domain deleted. Biochemical and cell culture experiments show that this decoy 3′ acceptor site interacts nonproductively with the 5′ splice site of the alternative exon 9, thus repressing the efficient use of the 5′ splice site of exon 9 despite a high level of U1snRNP binding to this 5′ splice site. Downstream of the decoy 3′ splice site resides the second functional domain that interacts with PTB. The binding of PTB to CU-rich motifs within this downstream domain juxtaposed to the decoy 3′ acceptor site correlates well with the repressor activity of this domain. PTB can modulate recognition of the adjacent decoy 3′ acceptor site. In addition to factors interacting with an authentic 3′ splice site (such as U2AF or U2snRNP), PTB as well as other proteins interact with In100 and contribute to recognition of the In100 decoy 3′ splice site by the spliceosome as an intronic repressor element, rather than as an authentic 3′ splice site. The regulatory role of PTB in casp-2 alternative splicing and its mechanism of action appear to be distinct from other systems (Sect. 2.2.2). A recent survey of known human genes involved in cell death regulation suggests that In100-like intronic elements (i.e. 3′ splice site juxtaposed to PTB-binding domains) may represent a general intronic splicing repressor motif. Such intronic elements

may play a role in regulating alternative splicing of other cell-death genes.

Another example of the complexity of splicing regulatory elements is in the alternative splicing of exon 10 in the human *tau* gene. Alternative splicing of this exon is associated with the pathogenesis of dementias (Sect. 3.1). In this case, both exonic and intronic regulatory elements play important roles in controlling exon 10 inclusion. In addition, in the exonic region, both positive and negative elements are involved and form a multidomain composite regulatory element.

2.2.2 **Trans-acting Splicing Regulators**

The recognition and selection of splice sites are determined during spliceosome assembly, especially at early steps of spliceosomal formation. Splicing activators facilitate interaction of U1snRNP with 5′ splice site and of U2snRNP with 3′ splice site, whereas splicing repressors suppress the recognition of splice sites. A number of proteins involved in spliceosome assembly also play important roles in regulating alternative splicing (see Table 1).

Several families of splicing activators have been reported (Table 3). SR proteins are among the best characterized splicing activators. The interactions between SR proteins and ESEs play a critical role in exon recognition by the spliceosome. ESEs are present in both constitutively and alternatively spliced exons. By mediating protein–protein and RNA–protein interactions during early steps of spliceosome assembly, SR proteins coordinate the communication between 5′ and 3′ splice sites and promote interactions between exonic enhancers and splice sites. Enhancer complexes are usually multicomponent complexes, containing not only SR proteins but also other RS domain–containing proteins such as U2AF. Some RS domain–containing proteins, such as SRm300 and SRm160, act as coactivators for ESE function. The RS domain in SR proteins can be differentially phosphorylated, providing another level of regulation. The phosphorylation status of SR proteins regulates protein–protein interactions, intracellular distribution, and activities of SR proteins. Differential phosphorylation of SR proteins has been shown to play a role in regulating gene expression during development.

SF1, KSRP, NOVA-1, and rSLM-2 are RNA-binding proteins containing heterogeneous nuclear ribonucleoprotein K-type homology (KH) domain. They can enhance splicing by interacting with ISEs. SF1, a protein important for branch site recognition during spliceosome assembly, binds to GGGGCUG repeats in an ISE to activate the recognition of a 6-bp micro exon in cTNT gene. KSRP interacts with UGCAUG sequence and stimulates the neuronal-specific exon inclusion in c-src. NOVA-1 enhances the splicing of exon E3A in the $\alpha 2$ subunit of the glycine receptor gene (GlyR$\alpha 2$). The rat Sam68-like mammalian protein (rSLM-2) is a member of the STAR (signal transduction and activation of RNA) protein family. It can influence the splicing pattern of the CD44v5, human transformer-2beta, and tau minigenes in transfected cells.

Several members of CUG-BP and ETR-like factors (CELF) family activate the splicing of genes including cTNT, muscle-specific chloride channel, insulin receptor, and NMDA R1. Some of these CELF proteins activate splicing by interacting with ISEs.

TIA-1, a mammalian homolog of yeast NAM8 protein, interacts with the U-rich intronic sequence adjacent to the 5′ splice site of the K-SAM alternative exon in the FGFR2 gene. The activation of this splice

site is U1snRNP-dependent, and TIA-1 may function by facilitating U1-snRNP binding to the 5′ splice site.

Human Y-box binding protein (YB-1) was initially identified as a transcription factor interacting with single-stranded DNA in response to cold shock. YB-1 contains a five-stranded ß-barrel known as the ''COLD'' domain and accessory domains rich in basic amino acids and aromatic groups. This domain arrangement in YB-1 protein with specific interaction domain containing ß-sheets and a basic domain providing generic RNA binding is reminiscent of the modular structure of the SR proteins. YB-1 stimulates the splicing of the human CD44 alternative exon v4 by interacting with the A/C-rich element in the exonic splicing enhancer. Another protein, DEAD-box RNA helicase p72, has been reported to affect the splicing of alternative exons containing AC-rich exon enhancer elements. The mechanism of YB-1 or other proteins interacting with the A/C-rich type of ESEs in splicing activation remains to be elucidated.

HnRNP proteins hnRNPA1 A1 and PTB are among the best characterized splicing repressors. HnRNP A1 can interact with either ESSs or ISSs to prevent exon recognition by SR proteins or U2 assembly. A model has been proposed for interactions between hnRNP A1 and ESS based on studies on HIV Tat exon 3 splicing. In this model, the high-affinity binding of hnRNPA1 to ESS promotes nucleation of multiple A1 along the exon. The formation of this inhibition zone can be blocked by SF2/ASF, but not by another SR protein SC35, providing an explanation for differential antagonism between hnRNP A1 and different SR proteins. Two different models have been proposed for the function of hnRNPA1 in splicing silencing mediated by ISSs. In the case of HIV Tat intron 2 splicing, the interaction of hnRNP A1 with an alternative branch point sequence blocks the recognition of the branch site by U2snRNP. In the second model, the cooperative binding of hnRNP A1 to two intronic elements flanking the alternative exon inhibits exon inclusion by a looping-out mechanism during autoregulation of hnRNP A1 gene splicing.

PTB interacts with U/C-rich elements in ISSs in a number of genes including n-src, FGFR2, $GABA_AR\gamma 2$, tropomyosin, NMDA R1 exon 5, clathrin light chain B, caspase-2, and calcitonin/CGRP genes. Depletion of PTB using an RNA interference approach demonstrates that PTB is a negative regulator of exon definition in cultured cells. PTB-binding sites are frequently located in the intronic regions upstream of the regulated 3′ splice sites, although functionally active PTB-binding sites are also found in intronic elements downstream of the alternatively spliced exons (such as in c-src and caspase-2 genes). Mechanisms by which PTB represses splicing are not clear yet. One model for repression by PTB is via competition with U2AF binding to the polypyrimidine tract to block early spliceosome formation. This model is based on studies of alternative splicing of $GABA_AR\gamma 2$, NMDA R1 exon 5, and clathrin light chain B genes. In these genes, the high-affinity PTB binding to the long polypyrimidine tracts immediately upstream of the neural-specific exons represses the inclusion of these exons in nonneural tissues. A similar repression mechanism may be used in suppressing the inclusion of muscle-specific exons in rat α- or β-tropomyosin. PTB exists in a range of different tissues as an abundant splicing repressor. The repressor activity of PTB may be modulated by other regulatory proteins. Two tissue-specific PTB-related proteins have

been found, neuron-enriched (nPTB,) and smooth muscle–enriched (SmPTB). For example, nPTB can compete with PTB to promote inclusion of neuronal-specific N1 exon inclusion in c-src. The expression of SmPTB correlates with the smooth muscle–specific suppression of α-tropomyosin exon 3, which is included in nonsmooth muscle cells. The release of PTB suppression can be also achieved by cell-type specific CELF proteins such as ETR3 and Napor-1.

One exception to the general inhibitory activity of PTB has been reported where PTB stimulates the inclusion of an alternative 3′-terminal exon. In this case, the splicing regulation is coupled with alternative polyadenylation. In addition, PTB has also been implicated in translational control of viral transcripts. More comprehensive understanding of the biological roles of PTB in gene regulation requires further investigation.

Several proteins containing an RS domain and RRM-cs domains have also been reported to act as splicing repressors, including SRrp30c, SRrp35, SRp38, and SRrp40 (see Table 3). SR proteins are generally hyperphosphorylated by the kinase SRPK1. Dephosphorylated SRp38 is required for the splicing repression in mitotic cells. Another RS domain-containing protein, the *Drosophila* suppressor-of-white-apricot protein (SWAP) suppresses its own pre-mRNA splicing.

An RRM-containing spliceosomal protein, SPF45, represents a late-acting splicing regulator. In *Drosophila*, SPF45 blocks splicing at the second step by interacting with Sex-lethal (Sxl) protein, indicating that 3′ splice site recognition and splicing regulation can occur at the second catalytic step.

Proteins containing KH domains can also act as splicing repressors. For example, a nuclear isoform of quaking (qk) protein, QKI-5, regulates alternative splicing of myelin-associated glycoprotein gene by interacting with an intronic splicing repressor element. A *Drosophila* splicing repressor, P-element somatic inhibitor (PSI), is required for the soma-specific inhibition of splicing of P-element pre-mRNA both *in vitro* and *in vivo*.

Several splicing regulators can act as either positive or negative splicing regulators, depending on the sequence context of the pre-mRNA substrates. We classify these splicing regulators as bifunctional splicing regulators. Some SR proteins or SR-domain containing proteins can repress splicing of certain pre-mRNAs but activate splicing of other substrates. SRrp86 is an 86-kDa related to SR proteins. It can function as either an activator or a repressor by regulating the activity of other SR proteins. Other proteins can repress splicing by interacting with SR proteins. For example, an ASF/SF2-interacting protein, p32, was shown to act as a splicing regulator by inactivating the function of ASF/SF2.

HnRNP H and the related protein hnRNP F contain three RRMs of RNP-cs type. HnRNP H interacts with G-rich elements in either splicing enhancers or silencers. When binding to a splicing enhancer in the HIV env gene, hnRNP H acts as an activator by promoting the assembly of a complex containing SC35 and U1snRNP. When interacting with ESSs in the β-tropomyosin pre-mRNA or HIV Tat exon 2, or with a negative regulator of splicing (NRS) in the Rous Sarcoma Virus (RSV) genome, hnRNP H serves as a splicing repressor.

Napor1, a splice variant of ETR3, is expressed at a high level in the forebrain but at a low level in the cerebellum. Overexpression of Napor1 exerts opposite

effects on two different exons in NMDAR1, inhibiting exon 5 inclusion but stimulating exon 21 inclusion.

With more alternative splicing events characterized in detail, more cases of bifunctional splicing regulators may emerge. It is conceivable that these splicing regulators interact with different sequence elements and different spliceosomal components. When these interactions promote the productive recognition of splicing signals by the splicing machinery, such proteins act as splicing activators. On the other hand, when the same proteins compete with other splice activators or facilitate recognition of splicing silencers leading to nonproductive interactions between the spliceosome and splicing substrates, these proteins behave as splicing repressors.

2.3 Tissue-specific and Developmentally Regulated Alternative Splicing

Tissue-specific alternative splicing has been studied in mammalian systems for more than a decade. However, only a limited number of tissue-specific splicing regulators have been identified so far. These include Nova-1, Nova-2, nPTB, and SmPTB. Cell-type specific splicing regulators have also been found in *Drosophila* and *Caenorhabditis elegans*, such as neuronal-specific Elav (embryonic lethal and abnormal vision), ovary-specific Halfpint, and muscle-specific Mec8. From a large number of biochemical, molecular, and genetic studies, the emerging general theme is that no single factor dictates the tissue specificity of alternative splicing of any genes. Instead, multicomponent interactions among tissue-specific splicing regulators, pre-mRNA, and general splicing factors determine the specific alternative splicing pattern of a given gene in a tissue- or cell-type specific manner. On the other hand, genetic deletion of a single splicing regulator, even those highly tissue-specific ones, leads to defects in splicing of multiple target genes. For example, Nova-1 deletion in mice affects alternative splicing of $GABA_AR\gamma 2$, $GlyR\alpha 2$ and perhaps other unknown target genes. Similarly, the *Drosophila* neural-specific splicing regulator Elav has at least three known target genes, neuroglian (nrg), erectwing, and armadillo.

In addition to tissue-specific expression of splicing regulators, a number of other mechanisms modulate tissue-specific alternative splicing. Tissue-specific combination of different splicing regulators, relative concentrations of distinct splicing factors, and differential modification of splicing regulators all contribute to the tissue-specific alternative splicing of individual genes in a given tissue or cell type. For example, the level of the splicing repressor PTB in neural tissues is lower than in other tissues, providing an explanation for a more permissive environment for exon inclusion in a number of genes in neural tissues. Although most SR proteins are expressed in a wide range of tissues, their expression patterns vary in different tissues, both in different isoforms and at different levels. Many SR proteins have different isoforms either because of alternative splicing or posttranslational modifications. Kinases or phosphatases that regulate phosphorylation of different splicing factors can also be tissue specific. One example is the SR protein–specific kinase 2 (SRPK2), which is highly expressed in the brain and presumably capable of regulating activities of target SR proteins.

It is not clear yet how the extremely complex alternative splicing pattern of different genes in a given cell or a specific tissue is coordinated. In some cases, the alternative

splicing events of different genes appear to be coregulated by the same protein. For example, the splicing regulator PTB can differentially recognize neural and non-neural substrates. The expression pattern of PTB in different regions of the brain at different developmental stages supports a role for PTB to act as an alternative splicing coordinator for different splicing target genes.

2.4 Regulation of Alternative Splicing in Response to Extracellular Stimuli

Extracellular signals can induce changes in alternative splicing of different genes. For example, growth factors or hormones stimulate alternative splicing of intracellular responsive genes. Treatment with growth factors induces changes in alternative splicing of phosphotyrosine phosphatase PTP-1B gene. The alternative splicing pattern of protein kinase C beta is changed by insulin. Activation of calmodulin-dependent kinases (CaM kinases) stimulates changes in alternative splicing of BK potassium channels. In most cases, however, signal transduction pathways involved in splicing regulation have not been characterized.

A number of genes important for the functioning of the nervous system show activity-dependent changes in their splicing. Alternative splicing of syntaxin 3 changes in response to induction of long-term potentiation. NMDAR1 alternative splicing is modulated by both pH and Ca^{2+}. Stress hormones regulate alternative splicing of potassium channels. A cis-acting sequence named *calcium-responsive RNA element* (CaRRE) in the stress-inducible exon of BK potassium channels and in NMDAR1 exon 5 has been identified. This element mediates CaM kinase-dependent repression of the inclusion of the CaRRE-containing exons. The mechanisms by which the CaRRE causes exon skipping remain to be elucidated.

Drastic changes in the cell growth environment are expected to affect RNA metabolism, including alternative splicing. For example, ischemia in mice induces changes in alternative splicing of several genes examined. Accompanying such changes in alternative splicing are changes in the intracellular distribution of several splicing regulators. It is possible that these splicing regulators undergo changes in posttranslational modifications or at other levels induced by ischemia.

Chemical compounds, when administrated to animals or applied to cells in culture, can also cause changes in alternative splicings. Sodium butyrate has been tested in transgenic mice and shown to increase exon 7 inclusion of the SMN gene. Aclarubicin treatment induces changes in SMN gene alternative splicing in cultured cells. Treatment of A549 lung adenocarcinoma cells with cell-permeable ceramide, D-e-C(6) ceramide, downregulates the levels of Bcl-xL and caspase 9b splicing isoforms. The functional responses of nuclear splicing machinery to drug treatment opens the possibility of correcting aberrant or defective splicing using therapeutic agents (Sect. 4.2).

3 Pre-mRNA Splicing and Human Diseases

Aberrant pre-mRNA splicing has been implicated in the pathogenesis of a number of human diseases. Alterations, or dysregulation of either constitutive pre-mRNA splicing or alternative splicing can

cause disease phenotypes. Molecular genetic studies of human diseases have revealed a wide range of mutations that cause diseases because of their effects on pre-mRNA splicing. Investigating the molecular nature of these genetic defects and pathogenetic mechanisms will facilitate both diagnosis of such diseases and development of new therapeutic approaches.

3.1 Splicing Defects in Human Diseases

Genetic defects that cause aberrant pre-mRNA splicing can be found in every category of disease, from malignancies affecting a certain tissue or organ to diseases or syndromes involving multiple systems. Splicing mutations have been identified in genes involved in the pathogenesis of diseases in every system. Detailed information about these mutations can be found in databanks including HGMD (the Human Gene Mutation Database, http://www.uwcm.ac.uk/uwcm/mg/) as well as in a large number of publications. As shown in Table 4, we use a few examples to illustrate the diverse range of disease phenotypes and genes involved. The current understanding of these splicing defects will be summarized.

Malignancies are a major cause of mortality. Splicing mutations in genes critical for either cell proliferation or cell death result in malignancies in different systems. These include oncogenes, tumor suppressor genes, and genes involved in cell death. Only a few examples are included here to demonstrate the complexity of the involvement of defective/aberrant splicing in tumorigenesis. Cancer of the same tissue or organ can be caused by splicing mutations in different genes. For example, splicing defects in p53, p51, CD44, and members of epidermal growth factor receptor (EGFR) family lead to lung cancer, the most common cancer in humans. Breast cancer has been associated with splicing mutations in a number of genes, including HER-2/neu, p53, mdm2, and BRCA1 or BRCA2. Glioblastomas are also associated with splicing mutations in different genes. On the other hand, splicing defects in a single gene can lead to tumorigenesis in different tissues. For example, CD44 aberrant splicing has been associated with the development of a range of different tumors, such as breast cancer, prostate cancer, lung cancer, and Wilm's tumor. CD44 is a polymorphic family of cell surface glycoproteins important for cell adhesion and migration. Aberrant splicing of CD44 has been associated with the invasive behavior and metastasis of several types of tumors. Alternative CD44 splicing variants have been correlated with the poor prognosis of tumors. Another gene is Mdm2, whose alternative splicing defects have been implicated in oncogenesis in multiple tissues. Oncogenic splicing variants of Mdm2 that lack a domain important for its function in interacting with the tumor suppressor p53 have been found in breast cancer, glioblastoma, and rhabdomyosarcoma. Alterations in the balance of different FGFR2 splicing isoforms have been correlated with progression of prostate cancer. A significant fraction of neurofibromatosis type 1 (NF1) cases are associated with an aberrantly spliced NF1 gene. Production of tumor antigens as a result of alternative splicing has been associated with neuroblastoma and other tumors. The role of these tumor antigens in the development and metastasis of these tumors remains to be investigated. In pediatric acute myeloid leukemia (AML), splicing isoforms of gene fusion transcripts produced as a result of

Tab. 4 Examples of human diseases associated with aberrant or defective pre-mRNA splicing.

	Diseases	***Genes***	***Aberrant splicing***
Malignancies			
	Lung cancer	p53, p51, CD44, EGFR	Aberrant or defective splicing products
	Cancer in different tissues	p53, CD44	Defective or aberrant splicing isoforms
	Wilm's tumor	CD44	Aberrant splicing isoforms
	Breast cancer	HER2/neu	Aberrant splicing and imbalance of splicing isofors
	Breast and ovarian cancer	BRCA1, BRCA2	Exon skipping
	Breast cancer, rhabdomyosarcoma	Mdm2	Oncogenic variants lacking p53-binding domain
	Glioblastomas	Mdm2	Oncogenic variants lacking p53-binding domain
	Neurofibromatosis type 1	NF-1	Exon skipping
	Neuroblastoma	HUD, HUC, NNP-1, α-internexin	Production of tumor antigens
	AML	MLL-SEPTIN6	MLL-SEPTIN6 fusion-splicing variants
Cardiovascular diseases			
	Hypercholesterolemia	LDLR	Cryptic ss usage, exon skipping
	Hypertriglyceridemia	Hepatic lipase	Cryptic ss usage
	Marfan syndrome	Fibrillin-1	Cryptic ss usage, exon skipping
	Cardiomyopathy	cTNT	Aberrant splicing isoforms
	Hypertension	G-protein β3	Exon skipping
Metabolic diseases			
	Glycogen storage disease, type II	Lysosomal α-glucosidase	Cryptic ss usage
	Hereditary tyrosinemia, Type I	Fumarylacetoacetate hydrolase	Exon skipping
	Acute intermittent porphyria	Porphobilinogen deaminase	Exon skipping
	Ceruloplasmin deficiency	Ceruloplasmin	Cryptic ss usage
	Fabry's disease	Lysosomal α galactosidase A	Cryptic ss usage
	Tay–Sach's Disease	β-hexosaminidase	Intron retention, exon skipping
	Sandhof disease	β hexosaminidase β-subunit	Cryptic ss usage

	Diseases	***Genes***	***Aberrant splicing***
Neurodegenerative diseases			
	FTDP-17	Tau	Imbalance of splicing isoforms
	Alzheimer's disease	Presenilin-1	Exon skipping
	Alzheimer's disease	Presenilin-2	Exon skipping
	Ataxia telangiectasia	ATM	Cryptic ss usage
	Multiple sclerosis	CD45	Imbalance of splicing isoforms
	Spinal muscular atrophy	SMN1, SMN2	Exon skipping
	Retinitis pigmentosa	HPRP3, PRPF31, PRPC8	Unknown
Psychiatric disorders			
	Schizophrenia	$GABA_AR\gamma 2$, NCAM	Imbalance of splicing isoforms
	Schizophrenia	NMDAR1	Aberrant alternative splicing
	ADHD	Nicotinic acetylcholine receptor	Aberrant alternative splicing
Other syndromes or diseases			
	Cystic fibrosis	CFTR	Exon skipping
	IGHD II	GH-1	Imbalance of splicing isoforms
	Frasier syndrome	WT 1	Imbalance of splicing isoforms
	Epilepsy	AMPA receptor	Imbalance of splicing isoforms
	Menkes disease	MNK	Exon skipping
	Beta-thalassemia	β-globin	Cryptic ss usage
	Metachromatic leukodystrophy	Arylsulfatase A	Cryptic ss usage
	Myotonic dystrophy	DMPK	(CUG)n expansion:aberrant splicing

chromosomal translocation have been reported. Such aberrant gene fusion-splicing products may contribute to pathogenesis of tumors caused by chromosomal translocation. Finally, the development of drug resistance has been associated with changes in alternative splicing of members of multidrug resistance genes or genes involved in drug metabolism.

Cardiovascular diseases are among the leading causes of human death. Aberrant splicing of structural genes such as cTNT is associated with cardiomyopathy. Splicing defects resulting in the formation

of a defective receptor, such as the low-density lipoprotein receptor (LDLR), lead to familial hypercholesterolemia (FH). A single-nucleotide change altering the function of intracellular signal transduction molecules can cause diseases affecting multiple systems. For example, a single-nucleotide polymorphism leading to the formation of a G-protein beta3 subunit splice variant has been associated with hypertension. Aberrant or defective splicing can disrupt the function of genes encoding a wide range of proteins important for the function of the cardiovascular system, from cell surface receptors to intracellular signaling molecules. Both structural genes and regulatory genes can be affected by splicing mutations. These examples show that splicing mutations can affect development/formation of the cardiovascular system and regulation of cardiovascular system function.

A range of metabolic diseases is caused by splicing mutations, affecting the production of a single metabolic enzyme. For example, the glycogen storage diseases, Sandhof's disease, and Fabry's disease can be caused by the usage of a single cryptic splice site in the corresponding genes. Hereditary tyrosinemia (type I) and acute intermittent porphyria can develop because of improper exon skipping in the genes encoding for respective metabolic enzymes.

The critical role of splicing regulation for the normal function of the nervous system is demonstrated by the large number of neurodegenerative and psychiatric disorders associated with aberrant splicing. Splicing defects in *tau* and presenilin genes have been identified in different types of dementia, including frontotemporal dementia with parkinsonism linked to chromosome 17 (FTDP-17) and Alzheimer's disease. Splicing mutations that cause cryptic splice site usage in the ataxia telangiectasia (ATM) gene have been identified in ATM patients. Multiple sclerosis has been associated with imbalances of different splicing isoforms of CD45. A number of studies have shown that genetic mutations in ubiquitously expressed protein factors that affect spliceosome formation can lead to diseases with specific neurological manifestations, such as spinal muscular atrophy and retinitis pigmentosa. For example, mutations in SMN1 or SMN2 cause spinal muscular atrophy. Defects in genes essential for spliceosomal assembly, including HPRP3, PRPF31, and PRPC8, have been found in autosomal dominant retinitis pigmentosa. The molecular mechanisms underlying such neuronal-specific diseases caused by defects in the general splicing factors remain to be investigated.

Psychiatric disorders, including attention deficit/hyperactivity disorder (ADHD) and schizophrenia, have been associated with aberrant splicing. Imbalance of different splicing isoforms or aberrant splicing products of several genes were detected in the brain tissues of patients with schizophrenia. These genes include $GABA_AR\gamma 2$, NMDAR1, neuronal nicotinic acetylcholine receptors, and neural cell adhesion molecule (NCAM). Changes in splicing isoforms of astroglial AMPA receptors have also been reported in human temporal lobe epilepsy. Several other examples of diseases caused by splicing mutations or disregulation of alternative splicing are listed in Table 1, including cystic fibrosis, familial isolated growth hormone deficiency type II (IGHD II), Frasier's syndrome, Menkes disease, β-thalassemia, and metachromatic leukodystrophy. Again, a variety of aberrant splicing events in the corresponding genes cause

the formation of defective gene products and consequently the disease phenotypes.

3.2 Molecular Mechanisms Underlying Splicing Defects Associated with Disease

Genetic defects in pre-mRNA splicing that cause human diseases can be classified into two categories, cis-acting mutations that alter expression or function of single genes and trans-acting defects that affect the components of splicing machinery or regulators of alternative splicing. Both cis-acting and trans-acting splicing mutations can result in clinical manifestations, either primarily involving a single tissue/organ or affecting multiple systems. These mutations can cause diseases by their direct effects on single genes or by indirect mechanisms such as disrupting expression or regulation of multiple genes.

Cis-acting splicing mutations can cause diseases by either producing defective/aberrant transcripts or by simply altering the delicate balance of different naturally expressed splicing isoforms. Development of disease phenotypes can be the result of loss of function of the involved genes or gain-of-function toxicities associated with the aberrant gene products. A large number of studies have focused on relationships between cis-acting splicing mutations and specific defects in the formation or function of the affected genes. However, the relationship is much less understood between genetic defects in trans-acting splicing factors (such as spliceosomal components or splicing regulators) and specific disease phenotypes.

At least four types of molecular mechanisms have been described for cis-acting splicing mutations that cause human diseases (Fig. 6). These mutations often lead to the formation of defective protein products or the loss of function of the genes involved as a result of RNA or protein instability. Exon skipping is perhaps the most commonly reported mechanism for the production of defective gene products. Activation of cryptic splice sites has also been

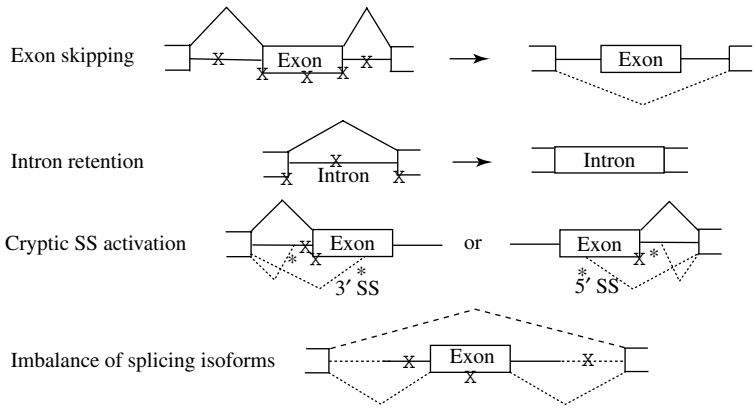

Fig. 6 Mechanisms for cis-acting splicing mutations. Positions of mutations are marked by "X," and they can be at the splice sites or within intronic or exonic sequences. The cryptic splice sites are marked by "*." Normal splicing events are illustrated by solid lines, and aberrant splicing events are depicted in dotted lines.

frequently associated with the production of aberrant or defective gene products. The failure to remove introns or intron retention is another mechanism for the formation of truncated protein products or the complete loss of gene function, because the inclusion of intronic sequences often introduces premature stop codons in gene transcripts. Finally, disturbance in the balances among naturally occurring splicing isoforms can lead to human disease. These mechanisms are not exclusive of each other. Multiple mutations acting by different mechanisms have been found in the same genes, leading to similar disease phenotypes. For example, both exon skipping and cryptic splice site activation contributing to the formation of defective LDLR lead to hypercholesterolemia. Similarly, exon skipping or cryptic splice site usage in Fibrillin-1 gene have been associated with Marfan syndrome.

Exon skipping can be caused by mutations at the splice sites or in splicing enhancers (either ESEs or ISEs). Translationally silent mutations can be functionally significant in splicing. For example, third codon changes that do not affect peptide sequences have often been overlooked as disease-causing mutations. Recently, such mutations have been examined at the splicing level. Such ''silent'' mutations may cause significant disruption in splicing, because defective function of ESEs leads to either improper exon skipping or imbalance of natural splicing isoforms.

Activation of cryptic splice sites in a large number of genes has been associated with human pathogenesis (see examples in Table 4). Single-nucleotide changes at the authentic splice sites result in inactivation of authentic splice sites. The consequences can be failures in exon inclusion or intron removal in some genes, or selection/activation of cryptic splice sites in other genes.

Intron retention has been examined in a number of disease genes. The average size of introns in human genes is approximately 3 kbp. The retention of even a small single intron may have catastrophic effects on the function of the genes affected because of the formation of defective or truncated peptides. Alternatively, intron retention can also cause a complete loss of expression of the mutated genes as a result of nonsense-mediated mRNA decay or instability of the gene products. Tay–Sach's disease can be caused by either intron retention or exon skipping in the splicing of the β-hexosaminidase gene.

Disturbance in the delicate balance of different natural splicing isoforms is now being recognized as a common mechanism for splicing diseases. It has been identified in neurodegenerative diseases, psychiatric disorders, and other diseases. These types of splicing defects can be caused by point mutations at splice junctions or in splicing regulatory elements (enhancers or silencers) located both in exon and intronic regions. FTDP-17, caused by mutations in the human *tau* gene, is a good example of such splicing defects. In addition to mutations that affect biophysical or biochemical function of Tau proteins, a large number of mutations that alter the ratio of natural splicing isoforms have been identified in FTDP-17 patients. The *tau* gene undergoes complex alternative splicing during the development of the nervous system. Six splicing isoforms are produced, three containing exon 10 and three lacking exon 10. These isoforms are named Tau4R and Tau3R respectively, because exon 10 encodes one of four microtubule-binding repeats. The balance among different Tau

isoforms is important for normal brain function, and disruption of the balance of Tau isoforms leads to the development of FTDP-17. Maintaining the appropriate balance of different Tau isoforms is controlled by complex interactions between the splicing machinery and various splicing regulatory elements in the *tau* gene. At the 5′ splice site of exon 10, a stem-loop type of secondary structure modulates the recognition of this 5′ splice site by U1snRNP. A number of intronic or exonic mutations destabilizing this stem-loop structure leads to an increase in Tau4R production. Other regulatory elements residing in exon 10, either splicing enhancers or silencers, may be disrupted by point mutations or small deletions, leading to the imbalance of different Tau isoforms. These mutations may increase (such as N279K) or decrease (such as L284L, del280K) the activity of the exonic splicing enhancer.

Other examples of diseases caused by disruption of the balance of different alternative splicing isoforms include Frasier syndrome, familial isolated growth hormone deficiency type II (IGHD II) and atypical cystic fibrosis. Such splicing defects have also been implicated in the pathogenesis of other diseases such as multiple sclerosis and schizophrenia. In Frasier syndrome, intronic mutations are found to change the ratio of +KTS to – KTS isoforms of Wilms tumor suppressor (WT1) gene products. The formation of these two splicing isoforms is the result of selection of two competing 5′ splice sites in exon 9. These two splice sites are separated by 9 nucleotides encoding KTS (lysine-threonine-serine). The use of the upstream and the downstream 5′ splice sites produces – KTS and +KTS isoforms, and the balance of these isoforms is important for kidney and gonad development. Mutations that decrease the use of the downstream +KTS 5′ splice site with an increase in the – KTS isoform have been associated with the majority of Frasier syndrome cases. These examples clearly show the significant role of splicing defects in human pathogenesis.

Spinal muscular atrophy (SMA) is an example that demonstrates the complexity of mechanisms underlying diseases caused by defects in trans-acting factors, such as proteins essential for spliceosomal snRNP biogenesis. SMA is a leading cause of infant mortality. Pathologically, it is characterized by degeneration of motor neurons in the anterior horn of the spinal cord leading to muscular atrophy. Genetic defects causing SMA include deletions or mutations in the survival of motor neuron genes (SMN). There are two copies of highly homologous SMN genes in humans, *SMN1* and *SMN2*. The *SMN1* gene is deleted or mutated in the majority of SMA patients. The SMN proteins are detected as distinctive speckles termed *gems* within the nucleus. SMN proteins contain an RNP1 motif and are critical for snRNP biogenesis and therefore, the formation of the spliceosome. Both SMN genes are expressed in a wide range of tissues. Although the predicted peptide sequences of *SMN1* and *SMN2* genes are identical, the gene products produced from the two genes in cells are different. A single translationally silent C to T nucleotide change at position +6 of exon 7 leads to the inefficient inclusion of exon 7 in the *SMN2* gene product, and thus the failure of *SMN2* to replace the function of *SMN1* and to provide protection against SMA. It is not clear why mutations in the *SMN* gene specifically cause motor neuron–specific disease. Although

the *SMN2* gene is not usually mutated in SMA patients, studies on stimulating *SMN2* exon 7 alternative splicing suggest a potential therapeutic approach based on the activation of alternative splicing of genes homologous to mutated genes (Sect. 4.2).

Myotonic dystrophy (DM), an autosomal dominant disease, is an example of trans-acting genetic mutations in which remarkable progress has been made. DM is a most common form of muscular dystrophy affecting both skeletal muscle and smooth muscles. Type I myotonic dystrophy (DM1) is caused by a CTG trinucleotide expansion in the 3′ untranslated region (3′UTR) of the DMPK (DM protein kinase) gene on chromosome 19q13.3. Type II myotonic dystrophy (DM2) is associated with a large CCTG repeat expansion in the intron 1 of the *ZNF9* gene. An ''RNA gain-of-function'' hypothesis has been proposed that these CTG or CCTG repeat expansions cause the formation of aberrant RNA transcripts containing large CUG or CCUG repeats. Such RNA transcripts containing long tracks of CUG/CCUG repeats may disrupt the normal function of certain RNA-binding proteins and induce secondary aberrant splicing of other genes. The RNA-binding proteins involved are likely to be the splicing regulators of CUG-BP family. The disruption of CUG-BP protein functions leads to aberrant splicing of genes including cardiac troponin T, insulin receptor, muscle-specific chloride channel, and tau. The aberrant splicing of these downstream genes can explain the cardiac phenotype, insulin resistance and myotonia found in DM patients. These findings demonstrate the complex roles of alternative splicing regulation in human pathogenesis.

Several trans-acting splicing defects have been reported in autosomal dominant retinitis pigmentosa (adRP). Recent genetic studies demonstrate that mutations in genes encoding general splicing factors such as HPRP3, PRPC8, or PRPF31 cause adRP. It remains unclear why these seemingly general defects in the splicing machinery cause such neuron-specific diseases. The underlying pathogenetic mechanisms await further investigation.

4
Perspectives on Diagnosis and Treatment of Diseases Caused by pre-mRNA Splicing Defects

4.1
Diagnosis of Human Diseases Caused by Splicing Defects

In the past three decades, significant advances have been made in the diagnosis of human genetic diseases, including diseases caused by splicing mutations. However, currently available molecular diagnostic tools remain limited for detecting splicing mutations.

Definitive diagnosis of splicing diseases should be based on the following criteria. First, the clinical manifestations should correlate with defects in a given gene. Second, corresponding splicing mutations are detected in genomic DNA samples of the patients. Third, aberrant or defective splicing products should be detected in the affected tissues or cells from patients. Detection of genomic mutations relies on DNA sequence analysis. In most cases, efforts in genomic DNA sequence analysis have been focusing on either exonic regions or near splice junctions. Detection of aberrant or defective splicing products

from patient samples can be technically challenging. The most frequently used methods include RT-PCR and analyses of defective protein products. In general, these methods are still limited to research studies. Systematic approaches to detecting disease-causing splicing mutations are yet to be developed for diagnostic applications in clinics.

4.2 Potential Therapeutic Approaches

Molecular studies and mechanistic characterization of splicing mutations that cause human disease have led to the development of a number of potential therapeutic approaches. They can be classified into four types, oligonucleotide-, ribozyme-, trans-splicing- and chemical compound-based approaches. These approaches are still at the stage of research and development.

4.2.1 Oligonucleotide-based Approaches: Antisense, RNAi, and Chimeric Molecules

Several groups have tested oligonucleotide-based methods for designing therapies to treat diseases caused by aberrant pre-mRNA splicing. These approaches include using modified antisense oligonucleotides or RNA interference (RNAi). Antisense oligonucleotides could be used to restore the proper function of mRNAs that are disrupted by splicing mutations. Antisense oligonucleotides designed to block cryptic sites in the mutated globin gene in β-thalassemia were reported to increase wild-type mRNA and decrease aberrant mRNA. A lentiviral vector-based system using a modified U7snRNA containing a sequence blocking the aberrant splice sites, reduced aberrant pre-mRNAs and increased levels of the correctly spliced β-globin mRNA and protein. The production of stress-induced aberrant AChE-R mRNA was reduced by antisense oligonucleotides. Another study using the antisense oligonucleotide approach reported the reversal of the aberrant splicing pattern caused by mutations associated with FTDP-17 in the human *tau* gene. On the other hand, antisense oligonucleotides have been used to increase the inclusion of exon 7 of SMN2 in order to develop therapeutic agents for spinal muscular atrophy. 2′-O-Methylated antisense oligoribonucleotides were used to modify the splicing pattern of the dystrophin pre-mRNA in the mdx mouse model of Duchenne muscular dystrophy. Recently, RNAi was used to selectively degrade alternatively spliced mRNA isoforms in *Drosophila* by treating cultured cells with dsRNA corresponding to an alternatively spliced exon.

One of most common splicing defects associated with human diseases is exon skipping. Because an RS domain can act as a splicing activator, small chimeric molecules containing a minimal synthetic RS domain covalently linked to an antisense moiety have been tested to target defective BRCA1 or SMN2 pre-mRNA transcripts and shown to restore splicing. These oligonucleotide-based approaches have shown feasibility in correcting splicing defects and treating the corresponding splicing diseases.

4.2.2 Ribozymes

Ribozymes are RNAs that catalyze biochemical reactions in cells, especially cleavage of other nucleic acids. Efforts have been made in developing derivatives from small naturally occurring RNAs, including the hammerhead, the hairpin, the tRNA processing ribonuclease P (RNase P), and group I and group II ribozymes as therapeutic agents. Ribozymes can be used to reduce aberrant or defective

splicing transcripts. In addition, a trans-splicing group I ribozyme was shown to convert mutant transcripts to normal mRNAs in the beta-globin and p53 genes.

4.2.3 SMaRT

Spliceosome-mediated RNA trans-splicing (SMaRT) was developed utilizing the endogenous trans-splicing activity in mammalian cells to correct aberrant splicing. SMaRT-mediated repair was reported to partially correct splicing defects in cystic fibrosis transmembrane conductance (CFTR) gene in cultured cells and bronchial xenografts.

4.2.4 Chemical Compounds

A number of chemical compounds have been shown to interact with RNA and/or RNA-binding proteins. Using chemical compounds to correct pre-mRNA splicing defects is being actively explored as a new therapeutic approach. Although the underlying mechanisms remain unclear, aclarubicin and sodium butyrate increase the inclusion of exon 7 in SMN2 transcripts in fibroblasts derived from spinal muscular atrophy patients or in transgenic mice, suggesting the therapeutic potential of chemical compounds in treating diseases associated with defective splicing.

Other chemical compounds are being tested that are capable of modifying splicing regulators, for example, kinases or phosphatases, that influence SR protein functions.

5 Concluding Remarks

After more than two decades of studies, a general picture of mammalian pre-mRNA splicing and alternative splicing regulation has begun to emerge. The basic components of the mammalian splicing machinery have been identified. The highly dynamic process of spliceosome assembly involves multiple networks of RNA–RNA, RNA–protein and protein–protein interactions. Recognition of splice sites and splicing regulatory sequences has been investigated in a number of genes, leading to identification and characterization of both cis-acting regulatory elements and trans-acting factors. We have begun to appreciate the contribution of alternative pre-mRNA splicing to creating genetic diversity, especially in mammals. A large number of splicing mutations that cause human diseases are being identified and characterized. We now have a glimpse of the complex picture of the involvement of aberrant or defective splicing in the pathogenesis of human diseases. Furthermore, efforts are being made to improve the diagnosis and treatment of diseases associated with pre-mRNA splicing defects.

Despite the significant progress, we are only at the beginning stage of understanding the molecular mechanisms controlling pre-mRNA splicing and alternative splicing regulation. A number of important questions remain to be addressed.

For the majority of genes, we have little knowledge about their complete expression profiles of different splicing isoforms in different cell types. We do not know how the splicing events of different genes are coordinated during development or in response to environmental changes. How a cell senses the environmental stimuli and responds by producing different splicing products remains largely unknown. Molecular pathways that transduce extracellular signals into the nuclear splicing machinery have not yet been delineated. Further development of new technologies such as

using microarray approaches to examine splicing isoforms under different physiological or pathological conditions at the genome level may be important for understanding the role of alternative pre-mRNA splicing in the biology of mammalian cells.

The basic components of mammalian splicing machinery are now characterized at the molecular level. However, the dynamic interactions among different components of the splicing machinery during spliceosome assembly and recognition of splicing regulatory elements are far from being understood. Little is known about the structural basis of such multicomponent interactions. Furthermore, the catalytic mechanisms of pre-mRNA splicing remain to be elucidated.

On the basis of studies of the relatively few model genes, a number of cis-acting elements and trans-acting splicing regulators have been identified. The mechanisms by which the splicing machinery specifically recognizes authentic versus decoy, or pseudosplice sites remain unclear. Some of the splicing regulatory factors are also important players for spliceosome assembly. Spliceosomal proteins also play a role in other processes of gene regulation. Further work needs to be carried out to understand the relationship between pre-mRNA splicing and other processes of gene expression and regulation, including transcription, RNA editing, RNA transport, translational control, and post-translational modification.

Studies of human diseases caused by splicing mutations or aberrant splicing have significantly advanced our understanding of human genetic diseases. Tremendous effort is still required to understand pathogenetic mechanisms underlying diseases caused by splicing defects, to develop efficient diagnostic tools and to design effective therapeutic approaches for these diseases.

Acknowledgment

We apologize to readers and our colleagues for having referred only to reviews instead of original research articles because of the space limit. The work in the authors' laboratory has been generously supported by Leukemia and Lymphoma Society, Muscular Dystrophy Association, Alzheimer's Association, the Society for Progressive Supranuclear Palsy, and NIH (AG17518, GM53945 and EY014576). We thank Drs Chris Burge, Reinhard Lührmann, Robin Reed, Phil Sharp, and Joan Steitz for sharing information and for giving permissions to modify figures from their previous publications. We are grateful to Drs Edward Benz, Doug Black, James Bruzik, Mariano Garcia-Blanco, Warren Gish, David Ornitz, Arnold Strauss, and members of Wu laboratory for their critical reading of the manuscript. We thank German G. Leparc, Joe Gee Seo, and Ying Zhang for the data bank searches and Mrs. Angie Hantak for outstanding assistance.

Keywords

Association Study
Tests for differences in allele or genotype frequencies between unrelated, affected, and unaffected individuals.

Autosomal Dominant Trait
A phenotype that is expressed in a heterozygote, which maps to a chromosome other than the sex chromosomes.

β-secretase
Also known as BACE1; a transmembrane aspartyl protease involved in processing of APP-generating N-terminal end of Aβ peptides.

Candidate Gene Study
An association study performed on a particular gene(s) selected according to the biology of the disease and/or their location within chromosome regions found to be implicated in disease (by linkage or association study).

Full Genome Scan
A linkage or association analysis performed between the disease and polymorphic markers that are spaced throughout the genome.

γ-secretase
A multiprotein complex involved in intramembranous cleavage of APP-generating C-terminal end of Aβ peptides. It contains four proteins: the catalytic component (presenilins) and three cofactors (nicastrin, APH-1, and PEN-2).

Neurofibrillary Tangles (NFTs)
Abnormal intraneuronal deposits abundant in the brains of patients with AD and some other neurodegenerative diseases. The main constituent of NFTs is hyperphosphorylated tau protein.

Senile Plaques
Complex extracellular deposits abundant in the brains of AD patients. The main proteinaceous component of plaques is amyloid-β peptide.

Susceptibility Locus/Gene
A region of a chromosome or a specific gene that may influence the risk to a certain condition/disease.

Familial Alzheimer's Disease
Transmitted as an autosomal dominant trait; usually has an age of onset $<$60 years.

Sporadic Alzheimer's Disease
Shows modest familial clustering and probably results from the synergistic action of genetic and environmental factors. Usually has an age of onset $>$60 years.

Abbreviations

Aβ	β-amyloid peptide
AD	Alzheimer's disease
AICD	APP Intracellular domain
APLP	amyloid precursor-like protein
APOE	apolipoprotein E
APP	β-amyloid precursor protein
BBB	blood brain barrier
CAA	cerebral amyloid angiopathy
CNS	central nervous system
CTF	C-terminal fragment
FAD	familial Alzheimer's disease
FTDP-17	frontotemporal dementia with parkinsonism linked to chromosome 17
KPI	Kunitz-type protease inhibitor
MT	microtubule
NFT	neurofibrillary tangles
NSAID	nonsteroidal anti-inflammatory drugs
NTF	N-terminal fragment
PDGF	platelet-derived growth factor
PHF	paired helical filaments
PS	presenilin
TM	transmembrane

Alzheimer's disease (AD) is the most common cause of dementia in the elderly. It is characterized by a progressive loss of memory, reasoning, judgment, and orientation, by the presence of large numbers of extracellular senile plaques and intracellular neurofibrillary tangles, as well as substantial cell loss in the brain. Genetic studies in early onset families have identified mutations in three genes that cause AD, while genetic studies in sporadic AD have identified the apolipoprotein E4 allele as a risk factor for disease. *In vitro* cell biology and transgenic mouse studies implicate all of these genes in the biology of Aβ metabolism. A consistent effect of these genetic factors is an increase in Aβ deposition. Furthermore, cell biology studies have identified targets for possible treatment of AD. Transgenic models are now being used to test the validity of these targets and therapeutic approaches to the treatment of AD.

1
Pathology and Epidemiology of Alzheimer's Disease

The German psychiatrist Alois Alzheimer first described the clinical and pathological features of Alzheimer's disease (AD) in a 55-year-old female patient; he published the discovery as a case report in 1907. It was thought that the ''presenile dementia'' described by Alzheimer was distinct from ''senile dementia'' seen in older patients, but it is now widely accepted that the two conditions are the same disease, differing primarily in the age of onset.

Alzheimer's disease is the most common cause of dementia in the western world, and the fourth leading cause of deaths in the United States. The disease is confined mainly to aged individuals and is progressive. It affects 1% of people in the developed nations and is likely to become a major problem in developing countries as the proportion of elderly persons increases in these populations. The incidence of AD rises with increasing age: 1 to 5% of people aged 65 years are affected, while 10 to 20% of those over the age of 80 have AD.

The first clinical manifestation is usually a loss of short-term memory; this is followed, over the next 6 to 20 years, by a progressive loss of memory, reasoning, judgment, and orientation (dementia). Death occurs, on average, about 10 years after the onset of symptoms. Many epidemiological surveys have been carried out to identify risk factors. There is a clear correlation between AD and a positive family history in about one-third of cases; the risk of AD is also elevated in individuals with Down syndrome. Severe head trauma with loss of consciousness increases risk for AD, particularly in those individuals who also have an apolipoprotein E4 allele. In contrast, the use of nonsteroidal anti-inflammatory agents or cholesterol-lowering agents, such as the statins, may reduce risk for AD. Another factor that may potentially decrease risk for AD is the years of education; the more the years of education, the lower the risk of disease.

Alzheimer's disease is characterized neuropathologically by the presence of large numbers of neuritic plaques and neurofibrillary tangles (NFT) within the brain cortex (Fig. 1). In addition, there is massive

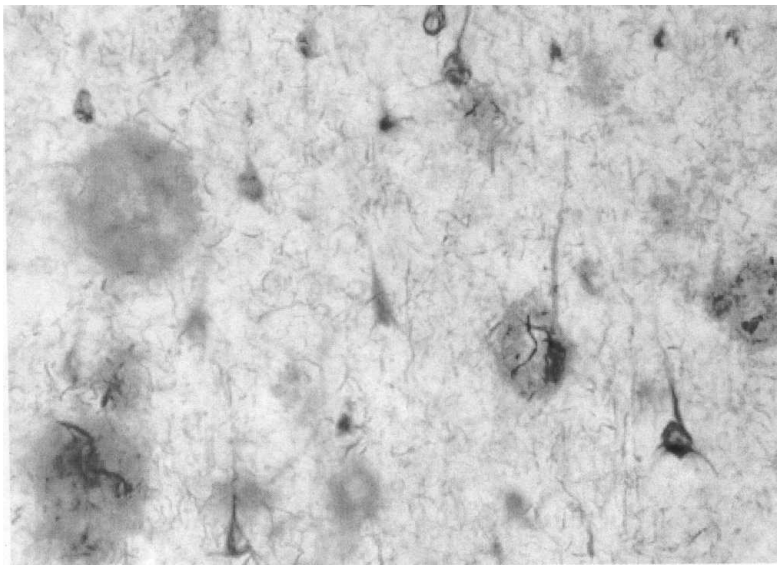

Fig. 1 Plaques and tangles in an AD brain. Shown is a brain section from an individual with mild AD. The section was double-stained with antibody PHF-1 specific to tangles and 10D5 specific to β-amyloid. Courtesy of Dr. Joel Price.

neuronal cell loss, and amyloid deposits that occur in the walls of the blood vessels of the meninges and cerebral cortex. Neither plaques nor tangles are specific to AD – they occur in intellectually normal, elderly people and in certain other diseases. However, they are more numerous and more widely distributed throughout the brains of Alzheimer's patients. Senile plaques are extracellular deposits, while tangles initially appear within the degenerating neurons. The major proteinaceous constituent of plaques is a 39 to 43 amino acid peptide called β-amyloid, or Aβ. The microtubule-associated protein, tau, is a major constituent of tangles. In the AD brain, there is extensive activation of astrocytes and microglia, the two primary mediators of inflammation in the central nervous system (CNS). A large number of inflammatory mediators and complement components are elevated in the AD brain, and colocalized with both plaques and tangles. The inflammatory response might be induced by increased Aβ levels or by plaque formation.

The deposition of Aβ has also been observed in association with several other pathological conditions. Individuals with Down syndrome, who live into their late thirties and beyond, develop a neuropathology indistinguishable from that of AD. Temporal studies in Down syndrome suggest that Aβ deposition is the earliest of the known pathological markers to appear, and that neurofibrillary tangles and neuronal cell loss occur decades after the first Aβ deposition. However, dementia correlates more closely with neurofibrillary tangles and neuron loss than with plaques. According to one hypothesis based on these observations, amyloid deposition precedes and induces tangle formation; tangles (and perhaps plaques) cause neuronal death, and the resultant neuronal damage destroys important

neurotransmission pathways in the brain, producing dementia.

2 The Genetics of Alzheimer's Disease

There are two forms of AD: familial Alzheimer's disease (FAD), in which the disease is transmitted as an autosomal dominant trait; and sporadic AD, which shows modest familial clustering and probably results from the synergistic action of genetic and environmental factors. Sporadic AD can have an early (<60 yrs) or late (>60 yrs) age of onset. FAD does not appear to be clinically or neuropathologically different from the more common sporadic form of AD, except that it generally has an earlier age of onset.

2.1 The Genetics of Familial Alzheimer's Disease

The existence of families in which AD segregates as a fully penetrant, autosomal, dominant trait presents the most striking evidence for the involvement of genetic factors in the etiology of AD. Mutations in three distinct genes, β-amyloid precursor protein (APP), *PS1* (presenilin 1) and *PS2* (presenilin 2) have been identified to cause FAD.

2.1.1 β-amyloid Precursor Protein Mutations

The main component of the AD-associated senile plaques, Aβ, is derived by the proteolytic processing of APP. The gene coding for APP is located on the long arm of chromosome 21. It contains 18 exons, three of which can be alternatively spliced to produce a variety of mRNA species.

The first mutation shown to cause FAD was a valine to isoleucine substitution at residue 717 of APP (Fig. 2). To date, 22 APP mutations have been reported, of which 17 are linked to early-onset AD (www.alzforum.org). Most mutations lie within the transmembrane (TM) domain of APP in the region that is involved in the generation of the C-terminal end of Aβ. All TM domain FAD-APP mutations result in an increased production of the longer, more amyloidogenic form of Aβ (Aβ42/43). The most severe mutation (T714I) causes a 11-fold increase in the Aβ42/Aβ40 ratio; it causes both a decrease in Aβ40 and an increase in Aβ42 production. Patients carrying the T714I FAD-APP mutation die in their 40s. FAD mutations in APP can differentially affect Aβ-peptide formation by either increasing Aβ42 or decreasing Aβ40, or both. The Swedish mutation (K670N, M671L) lies in the region outside of the TM domain in which cleavage by β-secretase generates the N-terminal end of the Aβ, resulting in an increase in both Aβ40 and Aβ42 levels. Five mutations are located within the Aβ sequence but outside the TM domain: Flemish (A692G), Dutch (E693Q), Arctic (E693G), Italian (E693K), and Iowa (D694N). Patients carrying these mutations deposit Aβ in senile plaques and/or in cerebral vascular walls (cerebral amyloid angiopathy – CAA) and present clinically with either AD or hemorrhagic strokes, or both. For example, Flemish A692G patients present with both AD and strokes, while most Dutch E693Q patients suffer from strokes followed by a progressive multi-infarct dementia (HCHWA-D, hereditary cerebral hemorrhage with amyloidosis Dutch type). Pathologically, Flemish A692G patients demonstrate a classical AD pathology although with a strong CAA component, while Dutch APP patients

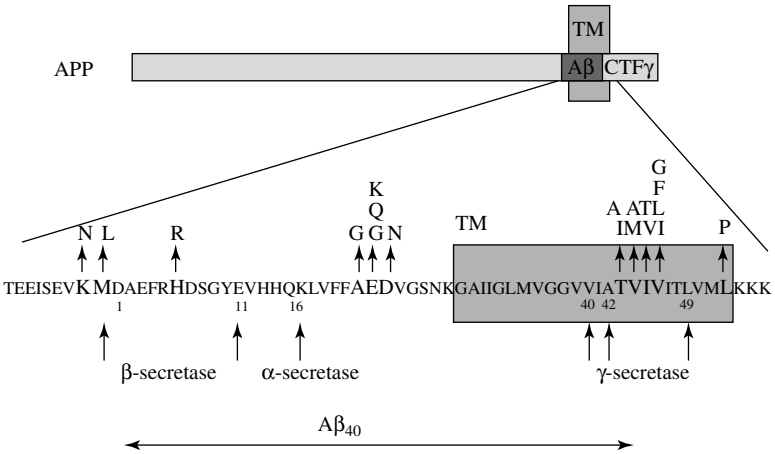

Fig. 2 FAD mutations in APP. Shown is a schematic representation of the APP protein showing the regions coding for Aβ peptide and C-terminal intracellular domain-CTFγ/AICD. The location of each FAD mutation is shown. Letters in bold are FAD-mutation sites, letters in gray are FAD substitutions. Major sites of APP processing, α-, β-, and γ-secretase sites, are also labeled. The amino acid numbering below the letters is according to the Aβ sequence.

have mainly vascular Aβ in the absence of neurofibrillary pathology. Recent analysis of pathogenic effect on Aβ levels of Arctic, Italian, Dutch, and Flemish APP mutations revealed that all, except the Flemish mutation, cause a decrease in both Aβ40 and Aβ42. In contrast, the Flemish mutation increases both Aβ40 and Aβ42 levels.

2.1.2 **Presenilin Mutations**

The discovery that mutations within the presenilin 1 *(PS1)* gene located on chromosome 14 (14q24.3) were responsible for most FAD cases opened up a whole new area of research into the molecular mechanisms of the pathogenesis of AD. Shortly after the discovery of *PS1*, DNA sequence database searches led to the identification of a homologous gene named presenilin 2 *(PS2)*, located on chromosome 1 (1q41.2). Mutations in *PS2* also result in FAD.

Pathogenic mutations in both of these genes have been identified; overall, mutations in *PS1, PS2,* and *APP* genes account for the majority of FAD cases. Although the proteins encoded by the two presenilin genes are 63% homologous at the amino acid level, intensive mutation and epidemiological analysis have revealed some interesting differences between the two proteins. The number of mutations identified in *PS1* is far greater than those in *PS2*. To date, more than 107 individual point mutations in *PS1* have been identified (Fig. 3, http://molgen-www.uia.ac.be/ADMutations) and found to be responsible for the majority of the early onset FAD. Most of these alterations are missense mutations that result in single amino acid changes in residues that are conserved between the PS1 and PS2 proteins. An intronic mutation (referred as ΔE9) results in the disruption of a splice acceptor site leading to the in-frame deletion of exon 9/10. This is the only *PS1*-FAD mutation that results in pathologically active protein that does not undergo proteolysis. Endoproteolytic

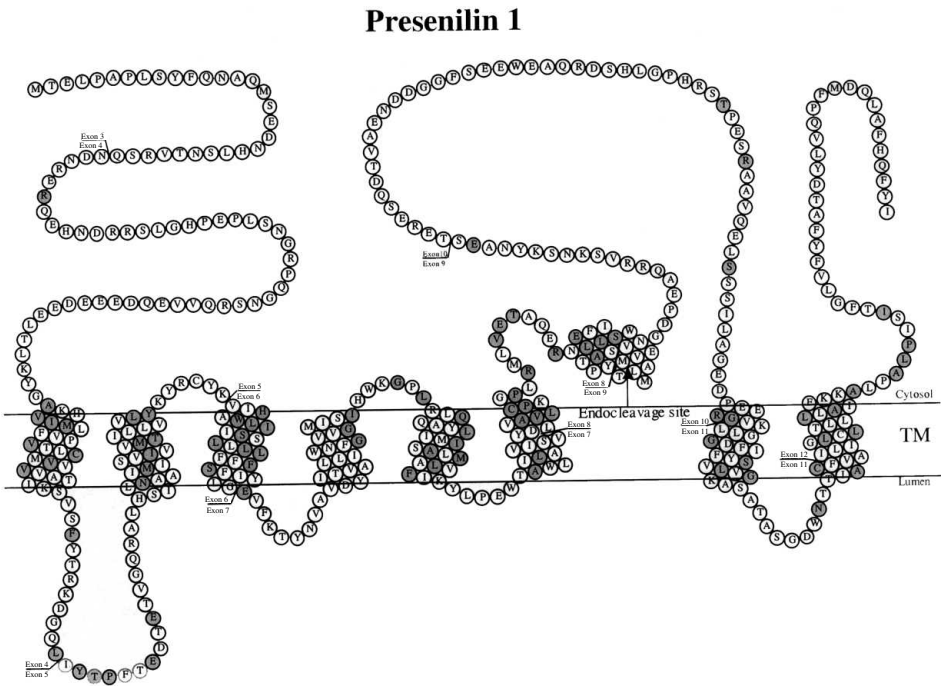

Fig. 3 FAD mutations in presenilin-1. Shown is a schematic representation of human presenilin 1 protein. The protein is predicted to have eight transmembrane domains. Arrow indicates the endocleavage site. Shaded residues are those associated with FAD mutations.

processing of the presenilins is an important aspect of the biochemistry of both PS1 and PS2 proteins, since it has been implicated in the formation of the functionally active complex (see Sect. 3). The most consistent effect mediated by the presenilin FAD mutations is increased production of Aβ42. This has been confirmed both in transfected cells and in transgenic mice. Although the mechanism by which FAD mutations in *PS1* and *PS2* cause AD is not fully understood, it is suggested that FAD mutations may alter γ-secretase activity toward cleavage of the more amyloidogenic peptide of Aβ, Aβ42/43. Although point mutations are distributed throughout the *PS1* gene, the majority of them are clustered within the TM domains and large hydrophilic loop between TM6 and TM7 (Fig. 3). The mean age of onset in all *PS1* families is about 45 years with a range of 28 to 62 years, suggesting that mutations in *PS1* result in a more aggressive form of FAD than APP mutations.

In contrast to *PS1*, only eight point mutations have been identified in *PS2* (http: // molgen-www.uia.ac.be / ADMutations). The first *PS2* mutation to be identified was the N141I mutation that is responsible for disease in a large Volga German kindred. Whether the preponderance of *PS1* versus *PS2* mutations is due to the differing genomic environment of the two genes or the factors related to differing biological functions of the two molecules, remains unclear. Mutation analysis of the

two proteins has also led to the identification of a phenotypic difference. Overall, the mutations in *PS1* result in relatively early and constant age of onset while those in *PS2* lead to a somewhat later and more variable age of onset. The identification of a *PS1* N135I mutation, a position and substitution that corresponds to the *PS2* Volga German mutation, and the finding that the affected members of this pedigree have a relatively constant age of onset suggests that the observed variations in age of onset are dependent on the molecule itself as opposed to the specific position or nature of the amino acid substitution.

2.2 The Genetics of Sporadic Alzheimer's Disease

While the genetics of FAD is fairly well understood, our understanding of the more common sporadic AD remains much less complete. The majority of cases have onset >60 years. Some families have stronger clustering of AD cases than others, suggesting that the genetic component of the disease can be quite variable. The estimated cumulative risk to first-degree relatives of AD-affected probands approaches 50% by age 90 compared to a disease risk of 10 to 15% in the general population. To date, only the Apolipoprotein *E*4 (*APOE4*) allele has been linked to increased risk for sporadic AD. While it is clear that *APOE* is a major risk factor for AD, epidemiological studies estimate that 42 to 68% of AD cases do not have an *APOE4* allele, indicating that additional genetic and environmental factors are involved in this form of the disease. The balance of these risk factors most likely determines both the age of onset of the disease and the number of affected first-degree relatives.

2.2.1 Apolipoprotein E

Linkage analysis in late-onset AD pedigrees led to the observation that these families inherit a genetic risk factor located on chromosome 19. The defect involved in these particular pedigrees is a susceptibility defect as opposed to a causative defect such as those present in the gene coding for APP and the presenilins. The inheritance of the susceptibility gene defect alone is not sufficient to cause the disease, and one or more secondary events, either environmental or genetic, must accompany the inheritance of the primary defect to cause the disease. Association studies have shown that the chromosome 19 susceptibility gene (localized to 19q13.2) is within the *APOE* gene locus.

APOE protein is a lipid-transport molecule and the primary apolipoprotein observed in the CNS. It is encoded by a polymorphic gene that exists as three alleles designated *APOE2*, *APOE3*, and *APOE4*. These genetic variations result in amino acid substitutions (arginine or cysteine) at positions 112 and 158 of the protein. Thus, whereas the *APOE2* polypeptide has a cysteine at both of these positions, *APOE3* has a cysteine at 112 and an arginine at 158, and *APOE4* has arginine at both positions. In most Caucasian populations, the *APOE3* is the most common allele (frequency 0.78); *APOE4* (frequency 0.14) and *APOE2* (frequency 0.08) are considered variants.

When the association of the three common *APOE* alleles with AD was examined in late-onset AD pedigrees, it was found that the *APOE4* allele frequency was 52%, compared to 16% for age-matched controls. In addition, in sporadic AD cases, the *APOE4* allele frequency was 40%. The *APOE4* association with AD was rapidly and widely confirmed in patients with familial and sporadic AD. These multiple

confirmations established the *APOE4* allele as the most important genetic marker of risk for the disease identified so far, accounting for approximately 50% of the genetic component of AD. The frequency of *APOE4* allele among AD and control cases can vary in different populations, however, the association with AD is consistent.

Individuals inheriting two copies of the *APOE4* allele have an increased risk and earlier age of onset of AD than individuals with one *APOE4* allele. Likewise, individuals with one *APOE4* allele have a greater risk and earlier onset of disease than those with no *APOE4* alleles. These data demonstrate that the effect of *APOE4* on risk and age of onset is dose-related. In contrast to the effect of *APOE4* allele, the *APOE2* allele has a protective effect on AD, as evidenced by a decreased frequency of this allele in AD cases. The effect of the most commonly inherited allele, *APOE3*, on risk and age of onset falls between *APOE4* and *APOE2*. There also appears to be an interaction of *APOE* genotypes with the age of onset in FAD. When survival analysis was used in a large Colombian kindred carrying a presenilin mutation, the presence of an *APOE4* allele was observed to decrease age of onset, while presence of an *APOE2* allele increased age of onset. Although it is still not clear how an *APOE4* allele modifies risk for AD, several studies suggest that APOE may act via an Aβ-dependent mechanism.

2.2.2 The Search for New Alzheimer's Disease Susceptibility Genes

There are two genetic approaches to finding susceptibility loci: full genome scans and candidate gene studies. In candidate gene studies, genes are selected on the basis of the known biology of the disease or their location within chromosomal regions implicated in risk for late-onset AD, and are assessed individually in order to determine whether variants in each candidate are associated with disease. An alternative approach, a genome scan, does not select genes *a priori*, but instead tests for linkage or association between the disease and polymorphic markers that are spaced evenly through the genome. Association methods use unrelated case-control samples or siblings who are discordant for disease, and test for differences in allele frequencies between affected and unaffected individuals. In contrast, linkage studies use extended families or affected sibling pairs and look for regions of the genome in which there is an increased allele sharing between affected relatives.

To date, only five late-onset AD genome-wide screens have been reported. The most consistent findings among these studies are evidences for AD susceptibility loci on chromosomes 19 (*APOE*), 9, 10, and 12. Since FAD is closely associated with elevated Aβ42 levels, some investigators have hypothesized that loci, which modify plasma Aβ42, might also modify risk for AD. Using this approach, evidence for linkage was observed in the same region of chromosome 10 as was observed in the AD-linkage studies. Over the past few years, a large number of biologically interesting candidate genes as well as candidate genes that map within chromosome regions implicated in risk for late-onset AD have been evaluated in case-control populations. The genes that have received most attention are those encoding *APOE* on chromosome 19, α2-macroglobulin and the LDL-receptor related protein on chromosome 12 and insulin degrading enzyme and urokinase on chromosome 10. All of these genes have been closely linked to Aβ metabolism. However, with the exception of the *APOE* gene, whose association with

AD has been universally replicated, the relative significance of these associations is still in question.

3 Molecular and Cellular Mechanisms Underlying Alzheimer's Disease

3.1 β-amyloid Precursor Protein

β-Amyloid precursor protein (APP) is a large, type I transmembrane protein that is expressed in almost all cell types except erythrocytes. It consists of a large extracellular N-terminal region, a transmembrane domain, and a short intracellular C-terminal tail. The Aβ-peptide sequence begins close to the membrane on the extracellular part of APP and ends within the membrane-spanning domain. At least five different mRNAs arise as a result of alternative splicing of the primary transcript of the APP gene: APP770, 751, 714, 695, and 563. Transcript APP695 lacks the Kunitz-type protease inhibitor (KPI) domain and is the major form expressed in neurons, whereas APP751, which contains the KPI domain, is the major transcript in non-neuronal cell types. The APP transcripts appear to be developmentally regulated, and all cell types so far tested contain at least one of the transcripts.

In addition to differential RNA splicing, APP undergoes posttranslational modification, including phosphorylation, N- and O-linked glycosylation, sulfation and proteolytic processing. It is not clear how these different events modify APP metabolism or function. A detailed knowledge of posttranslational events is undoubtedly crucial to understanding amyloid plaque formation and to elucidating the biological functions of APP and Aβ.

The normal function of APP is still unclear, but it has been implicated in neuroprotective action. APP is a member of a multigene family that contains at least two other homologs known as amyloid precursor-like protein 1 and 2 (APLP1 and APLP2). Both APP$^{-/-}$ and APLP2$^{-/-}$ mice are viable while APP/APLP2 double knockout mice are early postnatal lethal suggesting that APP and APLPs may share important physiological functions and the APLPs may compensate for the function of APP.

3.2 Production of Aβ – Proteolytic Processing of APP

It is clear that Aβ production does occur in normal cells, suggesting that excessive Aβ production in AD is due to enhanced or altered processing of APP by normal pathways that generate Aβ, rather than by an abnormal route specific to Alzheimer's cells. APP undergoes a series of proteolytic processing events (Fig. 4) by several different proteases called secretases. It is first cleaved by either α- or β-secretase. Two disintegrin metalloproteases, ADAM 10 and TACE (TNF-α converting enzyme), are involved in α-cleavage of APP. This cleavage produces a large soluble N-terminal fragment (NTF), APPsα and an 83-amino acid membrane-bound C-terminal fragment, C83 (CTFα). Alternatively, cleavage by the β-secretase results in an N-terminal fragment APPsβ and a 99-amino acid membrane-bound fragment, C99 (CTFβ). The β-secretase has recently been identified as a transmembrane aspartyl protease called BACE1, for β-site APP-cleaving enzyme. Both C83 and C99 are substrates for γ-secretase, a mysterious enzyme that carries out an unusual proteolysis in the middle of the transmembrane domain of

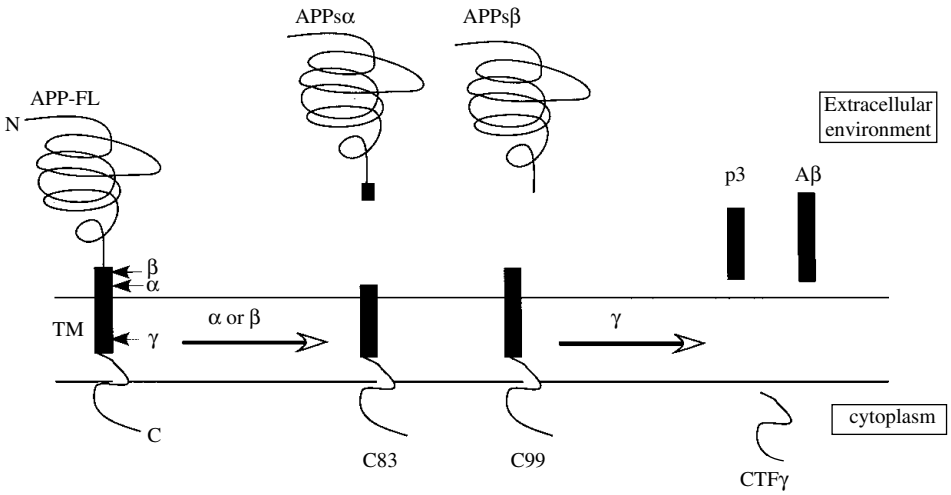

Fig. 4 Proteolytic processing of APP. APP is initially cleaved by either α- or β-secretase to generate membrane-bound C-terminal fragments, C83 or C99, which are subsequently cleaved by the γ-secretase (in the transmembrane domain) to produce p3 or Aβ.

APP, resulting in the release and secretion of the 4-kD Aβ from C99 and the 3-kD p3, a nonpathogenic peptide, from C83. γ-secretase cleavage is promiscuous and produces a spectrum of Aβ peptides varying from 39 to 43 residues in length. Over 90% of the Aβ in the brain is Aβ40 and the remaining 5 to 10% is the longer species Aβ42/43.

The C-terminal product of the γ-secretase cleavage is called CTFγ or AICD (from APP Intracellular Domain). Interestingly, CTFγ, purified from brain tissue, is not C59/57, which would be the predicted length of the C-terminal product of Aβ cleavage. Instead, sequence analysis reveals that it is C50/49, several amino acids shorter. The mechanism that accounts for such differential cleavages is currently under investigation. Several reports have suggested a role of CTFγ in APP signaling to the nucleus. Indeed, it was shown that CTFγ, when together with Fe65 protein, translocates to the nucleus and that this complex can activate transcription of a reporter gene *in vitro*.

3.3 β-secretase – BACE1

In late 1999, four groups almost simultaneously reported the discovery of BACE1, a novel aspartyl protease that exhibited all the known functional characteristics of the β-secretase. BACE1 is a type I transmembrane protein with an open reading frame of 501 amino acids. It is most closely related to the pepsin family of aspartyl proteases. BACE1 is expressed in most tissues and cell types at modest levels, but shows much higher expression levels in neurons. Structurally, it contains an N-terminal 21 amino acid signal peptide, a propeptide domain, a large lumenal domain followed by a transmembrane domain, and a short cytosolic C-terminal tail. BACE1 contains two aspartyl protease active site motifs in the lumenal domain: DTGS

(residues 93–96) and DSGT (residues 289–292). Both aspartic acid residues have been shown to be essential for enzymatic activity. BACE1 contains intrinsic proteolytic activity; as a purified recombinant, BACE1 can directly cleave APP *in vitro*. Overexpression of BACE1 in cell lines dramatically increases β-secretase activity and β-cleavage products: APPsβ and C99. In addition, mice deficient in BACE1 show a normal phenotype, but Aβ generation is abolished, further supporting that BACE1 is indeed a β-secretase.

BACE1 is initially synthesized in the ER as an immature precursor protein, proBACE1, which undergoes rapid maturation involving N-glycosylation as well as removal of the propeptide domain by a furin-like convertase in the Golgi apparatus. Unlike most zymogens, proBACE1 possesses β-secretase activity. The propeptide domain does not appear to significantly inhibit protease activity, but rather acts as a chaperone to assist proper folding of the protease domain. Phosphorylation of BACE1 at Ser498 appears to be important for the intracellular trafficking of the protein between early endosomes and late endosomes/TGN compartments.

A homologous aspartyl protease, BACE2 was shortly identified by searching the EST database with the BACE1 sequence. BACE1 and BACE2 share ~64% amino acid similarity. Together they define a novel family of transmembrane aspartyl proteases. Brain expression of BACE2 is very low and most evidence suggests that it does not play a major role in β-cleavage of APP.

3.4 γ-secretase – Presenilins and Cofactors

The enzyme that is clearly central to AD pathogenesis is the γ-secretase, which cleaves C99 and produces Aβ. Evidence suggests that it is an aspartyl protease with the unusual property of cleaving substrates within the transmembrane domain. Independent from its role in processing APP, γ-secretase also mediates the intramembranous cleavage of several other type I transmembrane proteins including Notch and ErbB-4. γ-secretase cleavage of Notch releases the Notch intracellular domain, which translocates to the nucleus and acts as a cofactor to modify transcription of target genes.

The identity of the γ-secretase is rather enigmatic. It appears to be a multiprotein, high molecular weight complex that consists of presenilins (PS) and three other cofactors: nicastrin, APH-1 and PEN-2.

3.4.1 Presenilins

Presenilins are a family of polytopic transmembrane proteins that are implicated in AD pathogenesis. PS homologs have been found in species as diverse as *Drosophila melanogaster*, *Caenorhabditis elegans* and *Arabidopsis*, but not in yeast. The function of PS appears to be conserved. Deficiency in sel-12, one of the nematode PS homolog, causes egg-laying defects. This phenotype can be rescued by expressing human PS1 in the mutant worms. In mammals, there are two PS genes, *PS1* and *PS2*, that share 65% identity. *PS1* is believed to account for the majority of PS functions, while *PS2* seems to play a complementary role.

Presenilins are found primarily within intracellular membranes including the ER and Golgi as well as the plasma membrane. Structurally, they are predicted to have eight transmembrane domains with both the amino and carboxyl termini oriented toward the cytoplasm (Fig. 3). A large cytoplasmic loop is postulated between TM6 and TM7. PS are synthesized as single

polypeptides that rapidly undergo endoproteolysis within the cytoplasmic loop, generating a 30-kD N-terminal fragment (NTF) and a 20-kD C-terminal fragment (CTF). The NTF and CTF form a stable complex, which appears to be the functional form of presenilins. PS endoproteolysis is tightly regulated such that overexpression of PS leads to the accumulation of a full-length protein, but does not result in an increase in the fragments. The NTF/CTF complex, but not the holoprotein, are components of a high molecular weight complex, estimated at ~250 kD or even larger. This high molecular weight complex is believed to be the γ-secretase complex.

Many lines of evidence indicate that *PS1* is the catalytic component of the γ-secretase. The two membrane-embedded aspartyl residues in *PS1* (D257 in TM6 and D385 in TM7) are essential for γ-secretase activity. The mutation of either residue abolishes γ-secretase processing of APP and Notch. The knockout of the PS genes blocks the Aβ production and Notch function. While in *PS1* single K/O cells, there is residual Aβ production, in PS1/2 double knockout cells, there is no detectable Aβ, demonstrating that there is no PS-independent γ-secretase activity. Inhibitors designed to be transition-state analogs of the γ-secretase bind to presenilin fragments. Recently, a family of signal peptide peptidases was discovered, which are apparently *bona fide* intramembranous aspartyl proteases, with similar active site motifs and similar topology to the presenilins. This finding further supports the hypothesis that presenilin is an aspartyl protease.

3.4.2 Cofactors

Nicastrin is a large type I transmembrane glycoprotein that was immunopurified from PS1 immunoprecipitates. It has no significant sequence homology to other functionally characterized proteins. Nicastrin is a 709 amino acid protein containing a putative signal peptide, a long N-terminal hydrophilic domain with numerous glycosylation sites, a TM domain and a short hydrophilic C-terminal tail of 20 residues. The mature protein migrates at ~150 kD owing to heavy glycosylation. There is evidence suggesting that the association of nicastrin with γ-secretase is tightly regulated via glycosylation. Nicastrin binds to presenilins and the active γ-secretase complex. Nicastrin deficiency in *Drosophila* abolishes Notch signaling and γ-secretase cleavage of APP. In addition, presenilin stability was compromised in the absence of nicastrin. All these data support that nicastrin is a component of the γ-secretase complex and an important regulator of the γ-secretase activity.

Genetic screens in *C. elegans* identified two proteins, APH-1 and PEN-2, which interact with worm homolog of *PS1* and nicastrin. Loss-of-function mutations of either protein produces phenotypes that resemble that of null mutants in nicastrin and presenilins. APH-1 is an integral protein containing seven predicted TM domains. There are two mammalian *APH-1* genes (*mAPH-1a* and *mAPH-1b*). *mAPH-1a* has at least two splice variants: *mAPH-1a*^{L} has seven exons and encodes a longer protein of 265 residues; mAPH-1a^{S} has six exons and encodes a shorter protein of 247 residues. All three variants are widely expressed, although their abundance seems to be coordinately regulated. To date, no functional difference among these variants has been documented. PEN-2 is a small protein of 101 amino acids containing two TM domains. Topology study suggests that both the N- and C-terminals of the protein face the lumen of the ER.

Human APH-1 and PEN-2 can partially rescue the *C. elegans* mutants, suggesting functional conservation among eukaryotes. The human genes must be present together to rescue the phenotypes and adding PS1 improves the rescue, indicating that these proteins act in concert. Consistent with the genetic studies, biochemical studies showed that reduction of APH-1 and PEN-2 expression in mammalian cells by RNA inhibition reduced γ-secretase activity.

While the exact functions of these cofactors remain to be elucidated, the data obtained so far suggest that all four proteins, presenilins, nicastrin, APH-1, and PEN-2, are necessary components of the γ-secretase. They appear to regulate one another for protein stability, proper maturation, and functional γ-secretase complex formation. It is also very likely that the least abundant component becomes the cellular-limiting factor that controls overall γ-secretase activity.

3.5 Neurofibrillary Tangles and Tau Protein

Neurofibrillary tangles are intracellular deposits that consist of aggregates of a fibrous substance, the paired helical filaments (PHF). These filaments are highly insoluble, even resistant to strong detergents such as SDS and guanidine hydrochloride. A major component of PHF is tau, a microtubule (MT)-associated phosphoprotein. Tau is abundantly expressed in the brain. At least six isoforms of tau are present in the brain, resulting from alternative mRNA splicing of a single gene on chromosome 17q.

Unlike APP, whose functions are not clear, tau has a biological role that is reasonably well understood. One function of tau is to promote microtubule assembly, a process controlled by phosphorylation of tau. In addition, it has been proposed that tau has a specific role in the generation of axon morphology. Increased phosphorylation of tau decreases its ability to promote tubulin polymerization to microtubules.

Tau in PHF is hyperphosphorylated, and is insoluble under conditions in which normal tau is soluble. It is believed that tangles are formed when tau becomes hyperphosphorylated and dissociates from microtubules and spontaneously forms insoluble PHF. Over 25 phosphorylation sites have been identified in PHF tau purified from AD brains. Most of the phosphorylation sites are located in the flanking region of the MT-binding domain. A variety of protein kinases, including glycogen synthase kinase-3β (GSK3β), cyclin-dependent kinase 5 (cdk5), mitogen-activated protein kinase (MAPK) and protein kinase A, have been found to be involved in hyperphosphorylation of tau. This suggests that multiple phosphorylation cascades may be activated in NFT-bearing neurons. However, it remains unclear whether these cascades are activated independently or whether one or more kinases are primarily responsible for initiating the cascade *in vivo*.

In addition to their presence in AD, filamentous tau inclusions accompanied by extensive gliosis and loss of neurons are the neuropathological hallmarks of other neurodegenerative diseases that are sometimes designated as tauopathies. There has been considerable debate in the AD literature concerning the primacy of Aβ versus NFT in the pathogenesis of AD. This was largely resolved by the identification of mutations in the tau gene in families with frontotemporal dementia with parkinsonism (FTDP-17). FTDP-17 is characterized clinically by the presence of

prominent behavioral changes early in the disease. The neuropathology associated with FTDP-17 is characterized by large numbers of NFT but no senile plaques. Mutations in the tau gene in FTDP-17 can alter splicing and produce a shift from the short tau isoform with three repeats to the longer isoform, which contains four repeats. Several other point mutations have been discovered in the coding region of tau that impact the functional integrity of the tau protein itself, P301L being the most common. So far, genetic analysis has not linked tau mutation directly to AD, but tau dysfunction may still have a significant role to play in the disease, if not in its initiation, then in its progression.

3.6 Apolipoprotein E

Apolipoprotein E is a 299 amino acid glycoprotein with a molecular weight of ~34 kD. Its N-terminal domain consists of four amphipathic α-helices and the C-terminal domain contains most of the lipid-binding activity. APOE is a major apolipoprotein that regulates cholesterol uptake and release. The CNS contains high levels of APOE with abundance only second to the liver. In the CNS, APOE is synthesized predominantly by astrocytes and is secreted into the CSF, where it is a major lipid carrier.

APOE appears to have multiple functions in the brain – any or all of which could potentially influence AD pathogenesis. The molecular mechanisms by which APOE protein is involved in AD pathogenesis are unclear because reports on the allele-specific effects of APOE are controversial. Nevertheless, numerous studies have demonstrated that APOE can affect AD pathogenesis either by influencing Aβ deposition or by a direct effect on neuronal survival. APOE is a major component of senile plaques and specifically binds to soluble Aβs. Allele-specific differences in Aβ binding, aggregation, and fibrillogenesis have been reported. Most histopathologic studies demonstrated a correlation between senile plaque density and *APOE4* allele dose in AD. Animal studies also show that APOE has isoform-specific effects on Aβ deposition and plaque formation (see Sect. 4.4).

There is also evidence that different alleles of *APOE* have different effects on neurite extension, neuronal survival, and the cell's response to oxidative stress. *In vitro* studies with primary neurons and neuronal cell cultures show that lipid-bound E3 promotes neurite extension, while E4 is neutral or inhibitory. These *in vitro* findings are consistent with reported defects in neuronal remodeling in AD brains carrying an E4 allele. APOE can have allele-specific differences on both neurotoxic or neuroprotective activities. High levels of APOE or some APOE synthetic peptides were shown to cause neurite degeneration or neuronal death in cultured cells, with the E4 having the most neurotoxic effects. On the other hand, APOE appears to play a role in protection against oxidative stress, a prominent phenomenon in AD pathogenesis. Apoe -/- mice exhibit increased markers of lipid peroxidation within the brain and appear to have increased susceptibility to neuronal damage. Different *APOE* alleles are shown to have isoform-specific neuroprotective effects (E2 > E3 > E4) on oxidative cytotoxicity caused by hydrogen peroxide, or Aβ peptides. A possible mechanism for the different antioxidant activities of the *APOE* alleles is their ability to detoxify 4-hydroxynonenal, a neurotoxic lipid-peroxidation product that is believed to play a key role in neuronal death in

AD. 4-hydroxynonenal covalently binds to APOE, with more binding to E2 and E3 than E4, probably because of the cysteine residues that are present in E2 and E3. E2 and E3 may therefore protect neurons by binding to, and thereby detoxifying, 4-hydroxynonenal.

4 Transgenic Mouse Models of Alzheimer's Disease

A major hindrance to basic research into the molecular pathogenesis of AD has been the absence of a mouse or rat model. As a result of the identification of mutations that cause AD in humans, this has begun to change. Although initial efforts to make transgenic models of AD failed, more recent efforts have recapitulated at least some of the key features of the disease. Many genetically altered mice have been designed to reproduce the neuropathology of AD, however, the majority of them share only some of the neuropathological and/or cognitive impairment characteristics of AD (http://www.alzforum.org). These include mice expressing human forms of the APP, the PS, APOE and, more recently, tau. Transgenic mice expressing human APP develop amyloid plaques, but neurodegeneration and neurofibrillary tangles are not observed. The Presenilin transgenic mice produced only increased Aβ42/43 levels and did not develop signs of AD pathology, even though the same mutations caused some of the earliest forms of inherited AD in humans. Strategies emphasizing tau resulted in increased phosphorylation of tau and tangle formation, although amyloid plaques were absent. Nevertheless, crossing transgenic animals expressing mutated tau and APP has produced a mouse that closely recapitulates the neuropathology of AD. This section provides a review of the various murine models and their role in understanding the pathogenesis of AD.

4.1 APP Transgenic Mice

The most extensively studied APP transgenic mouse lines are known as PDAPP and Tg2576. The PDAPP transgenic mouse expresses a human APP770 mini gene containing the V717F FAD-APP mutation, while Tg2576 expresses human APP695 that contains the Swedish FAD-APP mutation. In PDAPP, expression of the *APP* gene is under the control of the human platelet–derived growth factor (PDGF)-β chain neuronal promoter that targets expression preferentially to neurons in the cortex, hippocampus, hypothalamus, and cerebellum of the transgenic animals. This mouse was made on a mixed-strain background (C57BL/6, DBA/2, and Swiss-Webster), while Tg2576 was made on a single C57B6/SJL background. Expression of the *APP* gene in Tg2576 mice is under the control of the prion protein promoter resulting in a less-limited expression of APP both in the CNS and the periphery. The success of both models was due to the high level of APP expression achieved (>10-fold overexpression of human APP in PDAPP mouse and >6-fold higher expression of APP in Tg2576 compared to endogenous murine APP levels). Cortical and limbic amyloid deposits begin slightly earlier in the PDAPP mouse: by 3 months of age in homozygotes and at 6 to 9 months in heterozygotes, while in Tg2576 mouse they occur between 9 to 12 months of age, elevated Aβ production is observed as early as 3 months of age. Both models

develop β-amyloid deposits (in hippocampus and neocortex but limited in striatum and cerebellum), and the deposits are associated with dystrophic neurites, punctate immunoreactivity to hyperphosphorylated tau, astrocytosis, microgliosis, and vascular amyloidosis. The elevation of Aβ in the Tg2576 mouse correlates with the appearance of memory and learning deficits in the oldest group of transgenic mice as well. However, both APP transgenic models fail to show all the pathological features of human AD; no significant neuronal loss and no formation of NFTs were observed in either line.

Several other APP transgenic models were generated in order to obtain a complete or more comprehensive picture of the hallmarks of AD. The TgAPP22 transgenic mice overexpress a double mutant APP with Swedish (K670N, M671L) and London (V717I) FAD mutations in cis, while TgAPP23 only carries the Swedish mutation. In both models, the human APP751 isoform is used and its expression is under the control of the murine Thy-1 promoter. The TgAPP22 mice show twofold overexpression of the transgene over endogenous APP, and Aβ deposits were detected in the neocortex and hippocampus at 18 months of age, while the TgAPP23 has higher, sevenfold overexpression of human APP and typical Aβ plaques appear at the age of six months. Interestingly, these two murine AD models showed differences in plaque type; the majority of amyloid deposits in TgAPP22 mice brains are of the "diffuse" type, while in the TgAPP23 mice almost all extracellular amyloid deposits were fibrillar. Both substantial neurodegeneration and a reduction of neuron numbers were apparent in TgAPP23. In 14–18 months old TgAPP23 neuronal loss was 14% and reached 25% in mice with high Aβ plaque load. Additional pathological features included dystrophic neurites surrounding the plaques, hyperphosphorylated tau, but no NFTs developed.

Each of the models described above is remarkable in that the anatomical pattern of plaque formation parallels that seen in human AD. Furthermore, the morphology of amyloid plaques in aged APP-transgenic mice recapitulates amyloid pathology in human AD: the plaques span a continuum from diffuse Aβ deposits to compact core plaques with inflammation and neuritic dystrophy. However, none of these models reflects a complete picture of the neuropathology of AD.

4.2 Presenilin 1/2 Transgenic Mice

Several PS1 transgenic mice have been created to study presenilin biology *in vivo*. These mice differ in the promoter and the strains of mice used, but are similar in achieving high levels of protein production (1–3 fold over endogenous) in neuronal regions of the brain. Knockin transgenes were created expressing either the wild-type human PS1 or PS1 containing the FAD mutation A246E under the transcriptional control of the human Thy-1 promoter in PS1 null background. Both mice rescued the PS1 knockout mouse from embryonic lethality, confirming that PS1 mutation does not cause a loss of function of PS1 protein but has similar physiological properties as wild-type PS1. A second PS1 transgenic model expressing human mutant (M146L or M146V) and wild-type PS1 was generated under the control of the PDGF promoter. All three PS1 transgenics showed similar results: overexpressing mutant PS1 in the brains of transgenic mice lead to the elevation of

Aβ42/43, but not Aβ40. This effect was a direct result of the mutation and not overexpression of the human protein as the overexpression of the wild-type PS1 did not have any significant effect on Aβ levels. The physiological significance of the specific elevation of Aβ42/43 appears to be the observation that AD patients with PS1 mutations show plaques composed primarily of Aβ42/43. However, all three PS1 transgenic mice, in contrast to APP transgenics, revealed no Aβ deposition or other AD-associated pathology.

Recently, a PS1 mouse model carrying a PS1-P264L FAD mutation was developed using gene-targeting approach. The gene-targeted models are distinct from transgenic models because the mutant gene is expressed at normal levels, in the absence of the wild-type protein. $PS1^{P264L/P264L}$ mice had normal expression of PS1 mRNA, but levels of the N- and C-terminal protein fragments of PS1 were reduced while levels of the holoprotein were increased. $APP^{sw/sw}/PS1^{P264L/P264L}$ double gene-targeted mice had elevated levels of Aβ42, sufficient to cause Aβ deposition beginning at six months of age. This was the first animal model that exhibited Aβ deposition without overexpression of APP.

Three transgenic mice that express PS2-FAD mutation N141I under the control of PDGFβ chain promoter, chicken β-actin promoter or the neuron-specific enolase promoter were designed. The first two PS2 transgenic mice showed increased levels of Aβ42 in the brain of 12-month old mice. The third model utilizing neuron-specific enolase promoter did not show any difference in Aβ42 levels compared to the PS2 wild-type transgenic mice and both had no obvious differences in AD phenotypes (both had amyloid deposits).

4.3 Tau Transgenic Mice

One of the deficits of most AD transgenic models is the lack of tau pathology. APP and APP/PS transgenic mice, which exhibit extensive amyloid deposition also develop hyperphosphorylated tau around the amyloid deposits but it does not progress to resemble human NFTs. This suggests that some disruption of tau does occur in response to amyloid accumulation, but it does not progress to resemble human tauopathy in the mouse model. The idea that a species barrier prevents this progression has been proposed suggesting that primates and rodents differ in their response to injected amyloid not only in terms of neurodegeneration, but also in the accumulation of abnormal tau around the injected amyloid.

The most exciting development in the tau field is the creation of a transgenic mouse model with robust and reproducible tangle pathology. This transgenic mouse line, designated JNPL3, express human four repeat tau containing the most common FTDP-17 mutation, P301L, under the control of the mouse prion promoter. The mice develop motor and behavioral deficits that are associated with age- and gene-dosage-dependent development of congophilic NFT. Tau-immunoreactive pretangles are found in cortex, hippocampus, and basal ganglia, but at lower levels than commonly found in human disease. The tangles are associated with neurodegeneration, especially in the spinal cord where motor neurons were reduced by approximately 48%. This mouse has recently been used in breeding double and triple transgenic mouse models to produce a model system that more accurately recapitulates the hallmark pathology of AD (see further in the text). Recently, another

P301L tau transgenic model has been described that develops fivefold increase in the numbers of NFT soon after 18 days after the intracerebral injection of Aβ42 into the CA1 region of the hippocampus. These experiments indicate that an interaction of β-amyloid with the P301L tau mutation accelerates NFT formation.

4.4 Apolipoprotein E Transgenic Mice

A consistent consequence of carrying the *APOE4* allele is an increased number of amyloid plaques in the brain and more abundant amyloid deposition in the cerebral vasculature. The mechanism by which *APOE4* contributes to the development of neurodegeneration remains unknown, although the evidence suggests that this may be linked to the ability of APOE to interact with the amyloid β peptide and influence its concentration and structure. Recent studies with transgenic mice that overexpress the human APOE isoforms APOE2, APOE3, and APOE4 in a PDAPP hemizygous mouse (Apoe-/- background) show that isoforms that are known to increase the risk of AD enhance amyloid load and increase the neuritic pathology associated with fibrillar plaque development in aged animals (by 15 months of age APOE4 expressing mice having a 10-fold greater amyloid burden than APOE3 mice). The time course of Aβ deposition, Aβ levels, structure, and anatomic and subcellular distribution showed profound age-, species-, and isoform-dependent effect of APOE. It was also found that APOE not only impacts on the nature of aggregated Aβ, but also on the clearance of soluble Aβ from the brain across the blood–brain barrier (BBB). Aβ40 was rapidly cleared from the brain, while Aβ42 was cleared much less effectively, supporting the idea that Aβ42 production may favor amyloid deposition due to a reduced clearance across the BBB. However, Aβ clearance was not APOE isoform specific.

These recent findings are consistent with earlier work on Apoe null mice. When Tg2576 and PDAPP mice were crossed with Apoe null mice it was revealed that the absence of Apoe altered the quantity, character, and distribution of Aβ deposits in the transgenic animals, confirming that APOE affects the neuropathological phenotype in AD brains. The Aβ deposition is significantly reduced and is not thioflavine-S-positive.

4.5 Modulating and Enhancing the Phenotype: Transgenic Crosses

One of the great advantages of transgenic animals is that different mice can be mated together so that the effect of multiple transgenes on the disease phenotype can be observed. In particular, since most transgenic AD models do not exhibit all the pathological features of AD, different crosses have been made in order to design a model that will more closely describe the pathology, neurodegeneration, and memory loss seen in AD patients.

Double transgenic mice that carry *PS1-A246E* and *APPsw* FAD mutations show an elevated Aβ42/Aβ40 ratio in brain homogenates compared to the ratio observed in transgenic mice expressing *APPsw* alone or transgenic mice coexpressing wild-type human *PS1* and *APPsw*. In addition, double transgenic mice *APPswxPS1-A246E* developed numerous amyloid deposits much earlier (9 months of age) than age-matched mice expressing *APPsw* (18 months of age) and wild-type *huPS1* and *APPsw* alone. Interestingly, the majority of Aβ deposits in the double transgenic

mice were not immunoreactive to Aβ42 but instead were stained with antisera to Aβ40. Similarly, crossing the Tg2576 transgenic mice, which express mutant APPsw, with mice transgenic for *PS1-M146L* (PDPS1) revealed 41% increase in Aβ42/43 levels and formation of Aβ deposits in the cortex and hippocampus as early as 12 weeks of age, compared to development of Aβ deposits in Tg2576 mice of 9–12 months of age and approximately 1.5-fold elevation of Aβ42/43 from birth in PDPS1 line. The early Aβ deposits were found to be primarily composed of fibrillar Aβ and resembled compact amyloid plaques. As the mice aged, these fibrillar deposits did not increase substantially beyond the 12 months of age. Interestingly, the diffuse deposits appeared only until later, this is opposite to the general perception that in AD the compact deposits are formed by condensation of the diffuse material.

Studies on APPxPS1 double transgenics, therefore, revealed that marginal increases in Aβ42/43 levels, evoked by PS1 mutant transgene, can accelerate the deposition process by several months. As these mice have a severe Aβ pathology for an extended time relative to singly transgenic APP mice, other features of the disease such as tau abnormalities or major cell loss may become apparent as the animals age.

Double mutants produced from crossing JNPL3 transgenic mice expressing mutant P301L tau with Tg2576 mice expressing the APPsw mutation offered proof that Aβ influences the development of NFTs. The double mutant exhibited NFT pathology that was substantially enhanced in the limbic system and the olfactory cortex. These results suggest that APP or Aβ augments the formation of NFTs in the regions of the brain vulnerable to the formation of these lesions. Recently, a triple transgenic mouse was generated expressing APPsw, PS1-M146L, and P301L tau mutant protein that exhibited both plaques and NFT. However, other characteristics of AD such as neurodegeneration and memory loss have yet to be examined.

Although most of the transgenic models for AD do not completely recreate the disease phenotype, they have shown considerable utility, both for studying the disease mechanisms and for the preliminary testing of therapeutic agents, particularly those that are designed to modulate Aβ deposition.

5 Potential Treatments

The ultimate goal of AD research is to prevent disease and/or develop treatments for this devastating disease. Unfortunately, there is still no effective treatment available. Currently, the only FDA-approved therapy for AD is cholinesterase inhibitors, which can enhance cholinergic activity and temporarily improve cognitive function in some individuals in the early stages of disease. However, these drugs only treat the symptoms but have no impact on progression of the disease.

Recent advances in dissecting the molecular and cellular mechanisms that are involved in AD pathogenesis have provided substantial knowledge for determining novel targets for drug development. Several new therapeutic approaches targeted at distinct aspects of the disease are currently being pursued. Potential therapies include: anti-inflammatory agents, cholesterol-lowering drugs, antioxidants, hormonal therapy, and approaches that inhibit Aβ production or increase Aβ degradation and clearance. Strategies targeted directly at Aβ may be most effective

given the fact that Aβ deposition is the central and fundamental event that causes AD. Other approaches affecting downstream events in the neurodegenerative process are likely to be used as supplementary treatments.

5.1 Secretase Inhibitors

Two prime targets for drug development are β- and γ-secretases, the two enzymes that process APP to Aβ. Inhibitors to these two proteases are expected to have the greatest Aβ-lowering effect since inhibiting either enzyme can completely inhibit Aβ generation.

γ-secretase is considered to be central to AD pathogenesis because altering its activity invariantly favors Aβ42 production and causes AD. The major concern in developing a drug that targets the γ-secretase is its potential for side effects. It is clear that γ-secretase is important for several physiological functions through its role as the protease that mediates the intramembranous cleavage of a number of TM proteins, including Notch. One possible solution is to develop an inhibitor that selectively lowers Aβ (Aβ42 in particular) production without significantly affecting the cleavage of other γ-secretase substrates. The development of such inhibitors has been reported. Another possible approach is partial inhibition of γ-secretase activity, at inhibitor concentrations that reduce Aβ production without affecting Notch signaling. Indeed, it has been shown that compounds with no reported selectivity allow significant Aβ reduction without changing the Notch-related function. Some inhibitors, however, are reported to preferentially increase Aβ42 production when used at low concentrations.

Most evidence suggests that β-secretase (BACE1) may be a better therapeutic target than γ-secretase. BACE1 knockout mice do not generate Aβ, but are otherwise healthy and fertile without obvious deficits in the basal, neurological, and physiological functions. In addition, the X-ray structure of the BACE1 protease domain has been solved and should provide valuable knowledge for inhibitor design.

Although the knockout data are reassuring that the detrimental effects of inhibiting β-secretase may be minimal, concerns regarding the possible side effects remain. First, there are likely other β-secretase substrates since it is counterintuitive to assume that BACE1 has evolved just to generate Aβ. Indeed, one recent study suggests that β-secretase may be responsible for the cleavage and secretion of a Golgi resident sialyltransferase. It is very important to identify these substrates because they are valuable for predicting the possible side effects of BACE1 inhibitors. It will also be important to know the phenotype of BACE1/2 double knockout mice. Although BACE2 is not primarily involved in Aβ generation, it may have an important physiological role and inhibitors of BACE1 may also inhibit BACE2 because of the high degree of homology between these two proteins.

While inhibitors to both secretases may potentially be effective in AD treatment, the challenges facing drug development are significant. The inhibitors need to be highly selective for the target enzyme and target substrate to reduce possible side effects to a minimum. The inhibitors need to be able to efficiently cross the BBB. Potent peptide-based inhibitors to BACE1 have been developed. However, such large compounds are not viable drug candidates because they will not penetrate the BBB to a sufficient extent. Instead, the enzyme

inhibitors with therapeutic potential are preferably small organic molecules with high specificity. The X-ray structure of BACE1 suggests that its active site is more open and less hydrophobic than that of other aspartyl proteases. It may pose challenges for the development of small-molecule inhibitors.

5.2 Vaccine Approaches

Another novel approach for Alzheimer therapy is Aβ immunization. Many studies have shown that direct immunization with Aβ peptide or anti-Aβ antibodies can greatly reduce plaque formation, neuritic dystrophy, and other AD-like pathology in APP transgenic mice. One study also shows that such an immunization strategy is also effective in reversing behavioral deficits in the transgenic mouse model. It appears that antibodies to Aβ can enhance Aβ clearance, prevent Aβ fibril formation, disrupt Aβ fibrils, as well as block Aβ toxicity.

Despite the great effects in mice, there are serious concerns about the safety of this approach when used in humans. One concern is that autoimmunity may occur in humans, although it has not been reported in mice. Another major concern is the toxicity of Aβ42, which can cross the BBB and seed fibril formation in the brain, and therefore may actually promote plaque formation. In addition, Aβ42 may cause inflammation and neurotoxicity. A phase II clinical trial using Aβ42 vaccination was eventually terminated because of cerebral inflammation observed in several patients. The first autopsy result from this trial was just published. It shows exactly the two sides of this approach. Vaccination has such a powerful effect that the patient's cerebral cortex was almost cleared of Aβ deposition, but the side effect of cerebral inflammation was so severe that the patient developed meningoencephalitis, which led to death.

Safer therapeutic approaches including using nonamyloidogenic/nontoxic Aβ derivatives as an immunogen or passive immunization with Aβ antibodies are being developed. One study shows that passive immunization with $(Fab')_2$ fragments of Aβ-specific antibody can clear Aβ in a mouse model. This is promising because $(Fab')_2$ fragments do not interact with Fc receptors and so will not activate the cellular-immune response which has been the major cause for the severe side effects.

5.3 Other Therapeutic Approaches

Several FAD-approved nonsteroidal anti-inflammatory drugs (NSAIDs), including ibuprofen, indomethacin, and sulindac have been shown to selectively reduce Aβ42 levels in cultured cells. In addition, treatment of APP transgenic mice with ibuprofen reduces Aβ42 levels in the brain and suppresses plaque pathology. It appears that NSAIDs can subtly alter γ-secretase activity so that cleavage is shifted from Aβ42 to Aβ38.

Many studies also indicate that cholesterol influences Aβ metabolism and cholesterol-reducing drugs may have a beneficial effect on AD. Individuals taking cholesterol-lowering drugs such as statins show greatly reduced risk for developing AD, whereas individuals with elevated cholesterol are at a higher risk. Statins and other cholesterol-lowering drugs have been shown to reduce Aβ levels and Aβ deposition in both cell culture systems and animal models. The role of cholesterol in Aβ metabolism appears to be quite complex and the mechanisms are not clear.

Nevertheless, treatment with statins and other cholesterol-reducing drugs may have a significant clinical benefit in the prevention of AD.

6 Summary

We have seen a dramatic increase in our knowledge of the underlying molecular mechanisms of AD pathology during the last ten years. Understanding the effects of causative mutations in *APP* and the presenilins and the genetic risk factor, *APOE4* has led to the conclusion that changes in Aβ metabolism and deposition are central to the disease process. These studies suggest that similar mechanisms underlie both FAD and sporadic AD. Transgenic models of AD now provide a new hope for the rapid development in rational treatments for AD.

Keywords

DNA Microinjection
A gene-transfer technique utilizing micromanipulation to inject DNA constructs (transgenes) directly into the pronuclei or nuclei of cells. The foreign DNA integrates into the host cell genome at a random location and usually in concatemers. DNA microinjection is the most commonly used gene-transfer technique for creating transgenic mammalian species.

Embryonic Stem (ES) Cell Transfer
The transfer of genetically manipulable pluripotent embryonic stem cells into a developing embryo; achieved by microinjection of stem cells into blastocysts or coculture with earlier stage ova. The resultant transgenic animal possesses a proportion of cells descended from the embryonic stem ES-cell lineage. Gene targeting resulting in both loss-of-function (knockout) and gain-of-function (knockin) is possible. In mammalian species, this gene-transfer technique has been successful only in producing germ line transmission of ES cell lineages in mice.

Gene Transfer
A set of techniques directed toward manipulating biological function via the introduction of foreign DNA sequences (genes) into living cells.

Nuclear Transfer (Cloning)
The nucleus of a cell with organism-specific DNA is provided by a donor cell and introduced into an enucleated oocyte (unfertilized ovum) or zygote, allowing for reprogramming fate of the developing embryo.

Transgenic Animal
An animal either integrating foreign DNA segments into its genome following gene transfer, or resulting from the molecular manipulation of endogenous genomic DNA.

Transgenic Founder
The first-generation transgenic organism directly produced as a result of gene transfer/germ plasm manipulation procedures. The term does not imply that the transferred gene (transgene) is heritable to future generations.

Transgenic Line
A direct familial lineage of organisms derived from one or more transgenic founders, characterized by the passing of the transgene(s) to successive generations as a stable genetic element. The line includes the founder and any subsequent offspring inheriting the specific germ line manipulation.

Transgenic animals and our ability to manipulate the genome of whole animals *in vivo* have influenced the life sciences in dramatic fashion. In less than 15 years, practical aspects of germ line manipulation of the genetic composition of animals have allowed researchers to address fundamental questions in fields ranging from medicine and biology to biotechnology and production agriculture. Studies emanating from basic efforts in gene regulation have led the way to *in vivo* gene-transfer studies focused on the expression of foreign genes and the ablation of endogenous genes. Our appreciation of basic biological development in animals and the potential ramifications of novel phenotypes resulting from genetic engineering efforts have been markedly influenced by pioneering efforts in transgenic animal technology.

1 Introduction

1.1 Brief History and Definition of Transgenic Animals

The ability to introduce functional genes into animals provides a very powerful tool for dissecting complex biological processes and systems. Hence, transgenic animals represent unique models that are custom-tailored to address specific biological questions. Furthermore, classical genetic monitoring cannot engineer a specific genetic trait in a directed fashion. For identification of interesting new models, the genetic screening and characterization of chance mutations remains a long and arduous task. Therefore, gene-transfer is also of great value, particularly for animal species in which long life cycles reduce the value of classical breeding practices for genetic modification.

Although the entire procedure for microinjection into living cells was described in the late 1960s, it took 15 years before transgenic animals were created. In 1980 and 1981, six pioneering laboratories reported successful gene transfer and the production of transgenic mice. Their success would not have been possible, however, were it not for the refinement of recombinant DNA technologies needed to develop viable protocols and to document results. In gene transfer, animals receiving new genes (foreign DNA sequences

integrated into their genome) are referred to as ''transgenic,'' a term first coined by Gordon and Ruddle in 1981. As such, transgenic animals are recognized as specific species variants or strains, which result from the introduction and integration of new gene(s), or ''transgenes,'' into the genome. More recently, the term *transgenic* has been extended to chimeric or *knockout* mice in which researchers have selectively removed or modified a gene or genes within the host genome.

For years, many studies were envisioned – if only an animal genome could be readily modified. The realization of the many technologies at hand today has opened numerous avenues for research. Production of transgenic mice has marked the convergence of earlier advances in the areas of recombinant DNA technology and the manipulation and culture of animal germ plasm (Fig. 1). Transgenic mice provide powerful models to explore the regulation of gene expression as well as the regulation of cellular and physiological processes. The use of transgenic animals in biomedical, agricultural, and biotechnological fields requires the ability to target gene incorporation and to control the timing and level of transgene expression. Experimental designs have taken advantage of the ability to direct specific (e.g. cell, tissue, organ specificity) as well as ubiquitous (whole-body) expression *in vivo*. Furthermore, from embryology to virology, transgenic technology provides unique animal models for studies in various disciplines that would otherwise be all but impossible to develop spontaneously.

1.2 Applications of Transgenic Animals

A number of methods exist for gene transfer in mammalian species, including DNA microinjection, embryonic stem (ES) cell transfer, retroviral infection, blastomere/embryo aggregation, teratocarcinoma cell transfer, electrofusion, nuclear transplantation, spermatogonial cell transfer, and perhaps spermatozoa-mediated transfer.

Transgenic technology has been extended to a variety of animal species in addition to the mouse, including rats, rabbits, swine, ruminants (sheep, goats, and cattle), poultry, and fish. Transgenic amphibians, insects, nematodes, and members of the plant kingdom have also been produced. With advances in the understanding of promoter/enhancer elements and transcription/regulatory proteins involved in the control of gene expression, the technology continues to evolve using different model systems (Table 1). In the systems explored to date, gene-transfer technology is a proven asset in science as a means of dissecting gene regulation and expression *in vivo*. As such, the primary questions that are addressed, concern the roles of individual genes in development or in particular developmental

Tab. 1 Applications of transgenic mice.

Transgenic mice have provided models in biomedical, veterinary, agricultural, and biotechnological disciplines in the study of gene expression and developmental biology, as well as for
• the fields of embryology, endocrinology, genetics, immunology, neurology, oncology, pathology, physiology, toxicology, and virology;
• the study of genetic bases of disease, and the design and testing of therapeutic strategies;
• gene therapy;
• disease resistance in humans and animals;
• drug and product efficacy testing/screening;
• novel product development through ''molecular pharming''

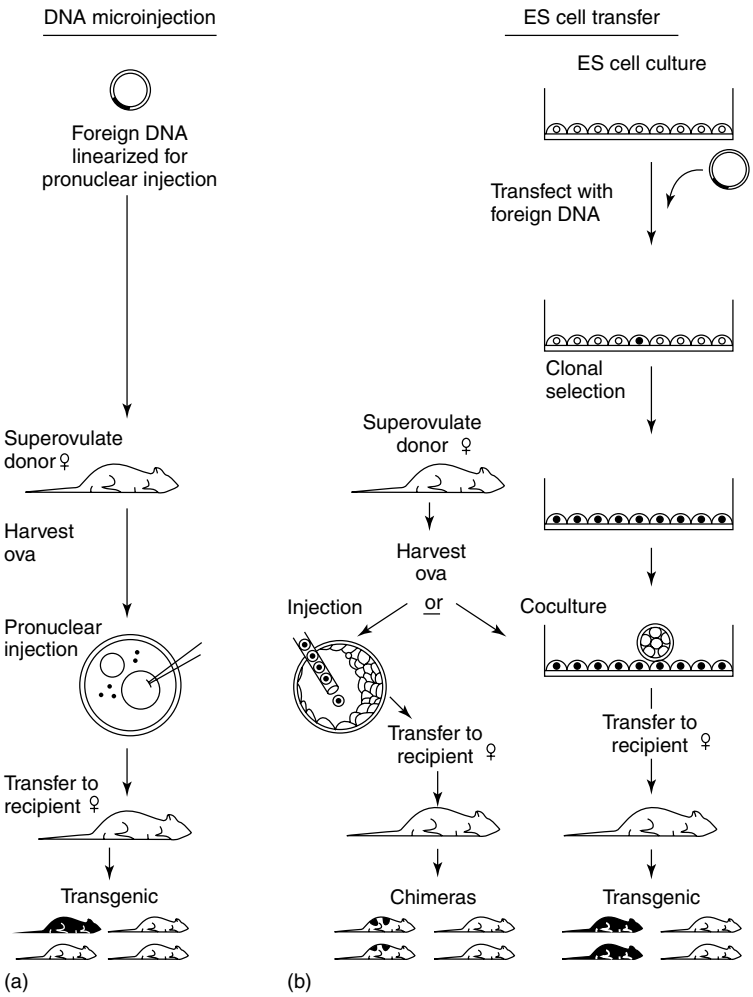

Fig. 1 (a) DNA microinjection and (b) embryonic stem (ES) cell transfer are the two most practiced methods for producing transgenic mice. Note that an *in vitro* culture step is not necessary for DNA microinjection; DNA is injected directly into the male pronucleus of fertilized one–cell ova (pronuclear zygotes). In general, if transgenic mice (represented by black mouse) are derived by DNA microinjection, all their cells will contain the new transgene(s). In (b), after clonal selection of transfected ES cells, one of two techniques is used for ES cell transfer. Ova are harvested between the eight-cell and blastocyst stages, ES cells are either injected directly into a host blastocyst (''injection'') or cocultured with eight-cell to morula stage ova, so that transfected ES cells are preferentially incorporated into the inner cell mass of the developing embryo (''coculture''). With blastocyst injection, transgenic offspring are termed *chimeric* because some of their cells are derived from the host blastocyst and some from transfected ES cells (denoted by white mice with black patches). Using coculture and tetraploid embryos, one can obtain founder mice derived completely from the transfected ES cells (denoted as all-black mice).

pathways. With this caveat, considerations include the ramifications of gene activity from intracellular to inter- and extracellular events within a given tissue or cell-type milieu.

Normally, gene function is influenced by cis-acting elements and trans-acting factors. For transferred genes, the cis- and trans-activators, in conjunction with the gene integration/insertion event within the host genome, influence regulation of both endogenous and transferred genes. Using genes that code for reporter proteins (e.g. oncogene or *lacZ*/βgal constructs), analysis of transgenic animals has revealed the importance of these factors in determining developmental timing, tissue distribution, and relative efficiency of gene expression. Transgenic animals have also proven quite useful in determining *in vivo* artifacts of other model systems or techniques.

There are a number of strategies in the development of transgenic mouse models, including systems designed to study dominant gene expression, homologous recombination/gene targeting and the use of ES cells, efficiency of transformation of eggs or cells, disruption of gene expression by antisense transgene constructs, gene ablation or knockout models, reporter genes, and marking genes for identification of developmental lineages.

1.3 Societal and Ethical Considerations

While gene-transfer technology continues to open exciting new biological frontiers, it also raises questions concerning regulation and commercialization. It is not within the scope of this presentation to fully address these issues; yet they do exist and will continue to influence the genetically engineered systems under development.

Contrary to the early prospects related to potential commercialization of this technology, there are societal challenges regarding perceived risks still ahead (Table 2). The risks at hand can be defined not only by scientific evidence but also in relation to public concern. Therefore, the central questions will revolve around the proper safeguards to employ and the development of coherent and unified regulatory guidelines. Can new animal reservoirs of fatal human diseases be created? Can more virulent pathogens be artificially created? What is the environmental impact of the "release" of genetically engineered animals? Do the advantages of a bioengineered product outweigh potential consequences of its use? These are but a few of the questions that we cannot ignore. Yet, the regulatory hurdles that exist today will challenge not only scientists and policy makers, but academicians, bioethicists, and legal scholars as well.

The strategies associated with the production of transgenic animals are quite variable, even between laboratories that utilize similar systems. However, most of the techniques for extensions to different systems are unique and timely

Patent aspects and product uniformity/economics of production

for new investigators. The overall efficiency of many procedures will vary, as will the cost–benefit ratios, however, one must not let the formidable challenges of gene-transfer experimentation outweigh the primary reason for instituting such studies – the desire to develop a biological model with specific genetic characteristics in a whole-animal environment.

2 Production of Transgenic Laboratory Animals

2.1 Choice of Animals

The relative importance of using particular strains or breeds of animals in gene-transfer experimentation will vary dramatically according to the species under consideration. Probably the most complex system is encountered in the production of transgenic mice, simply because so much work has been done with murine species. Here, well-documented differences in reproductive productivity, behavior, related husbandry requirements, and responses to various experimental procedures play major roles in determining the efficiency and the degree of effort associated with production of transgenic founder animals. A general discussion of these factors therefore serves as an appropriate starting point for understanding the many processes and procedures that must be evaluated and monitored when considering production of transgenic animals.

DNA microinjection, the most direct and reproducible method for producing transgenic animals, necessitates that several ''pools'' of animals be maintained for specific purposes. Most commonly, donor females are induced to superovulate by means of a regimen of injections of pregnant mare serum gonadotropin (PMSG, to stimulate follicular growth and development) followed by human chorionic gonadotropin (hCG, to induce ovulation of mature eggs). These donor females are then mated to fertile males, and large numbers of fertilized one-cell eggs (''zygotes'') are obtained surgically. Alternatively, ova may be collected from donor females and then subjected to *in vitro* fertilization (IVF) to obtain zygotes. In either case, the DNA construct, in a buffer solution, is microinjected into the male pronuclei of the fertilized eggs. Ova that survive microinjection are surgically transferred to the reproductive tracts of hormonally synchronous female recipients, which carry the embryos to term. In mice, DNA from offspring is isolated from tissue samples (e.g. tail biopsies) obtained at weaning and analyzed by Southern blot analysis and/or methods based on the polymerase chain reaction (PCR) to determine which individuals carry the transgene.

Certainly, the relative costs of different strains of mice that are chosen to serve as gamete donors or recipients is a factor. This must be balanced with the background genetics of the various strains and the effects these may potentially exert on expression of the integrated, foreign DNA construct (the transgene) and the resulting phenotype. Strains used for donor females are chosen for (1) numbers of eggs ovulated in response to hormonal superovulation regimen, (2) the relative uniformity of this response within the strain, (3) the viability of superovulated eggs both before and after microinjection, (4) the ease with which fertilized eggs are visualized and recovered from the reproductive tract, and (5) the morphology and/or size of pronuclei (which affects the

ease and speed with which eggs can be microinjected).

The strain chosen for embryo transfer recipient use is evaluated for (1) parenting ability, (2) docile behavior (which allows for inspection of pups or cross-fostering after birth), (3) ease of embryo transfer procedures, and (4) the regularity with which females exhibit readily detectable vaginal plugs and undergo a pseudopregnant response when mated with vasectomized males.

Obviously, the genetic background of the strain used for vasectomized males (and also recipient females) is less important, since these animals do not contribute to the genetic composition of the transgenic offspring. Strains are favorably considered in which vasectomized males exhibit libido and are able to form visible copulatory plugs in the recipient females both frequently (two to three matings/week) and with regularity over a period of about 12 months.

Conversely, intact males are chosen for their (1) libido, (2) absence of nonmating aggressiveness when placed with families, (3) fertility and capacity to produce visible copulatory plugs, and, if serving as IVF donors, (4) sperm concentration and quality. Finally, it is desirable to maintain a pool of synchronous, pregnant females that can serve as foster mothers in the event that recipient females begin to cannibalize pups or fail to adequately nurse their offspring.

For most other nonmurine species, it will remain important to use donor females that respond well to hormonal synchronization and superovulation, and to have recipients that are able to carry fetuses to term and care for neonates appropriately. However, differences in methods used for hormonal synchronization, selection of proestrus females, and evaluation of other forms of reproductive behavior may differ significantly from those identified for mice.

2.2 Gain-of-function, Loss-of-function and Conditional Modeling

With advances in the characterization of factors that control gene expression, gene-transfer technology has become an important means of dissecting gene regulation and developmental pathways *in vivo*. Normally, endogenous gene function is regulated by a variety of molecular factors. Analysis of transgenic animals has illustrated molecular underpinnings and events associated with developmental timing, tissue distribution, and consequences of modifying gene expression. Additionally, transgenic animals have also proven quite useful in validating an array of *in vitro*, *in vivo*, and theoretical model systems. Today, there are multiple modeling capabilities that allow a researcher to develop a given hypothesis revolving around a gain-of-function experiment (e.g. DNA microinjection, retroviral-mediated transgenesis, or knockin gene targeting procedures are used), a loss-of-function model (e.g. knockout gene targeting or overexpression of cellular toxins may be envisioned) or conditional systems (e.g. use of traditional temporally or spatially regulated transgenes, or where Cre-lox or other *in vivo* recombinase systems are employed).

2.3 Methodologies

2.3.1 DNA Microinjection

The microinjection method, referred to earlier, involves the use of micromanipulators and an air- or oil-driven microinjection

apparatus to physically inject the DNA construct solution into the male pronuclei or nuclei of fertilized one- or two-cell ova. As such, the method is also sometimes referred to as *pronuclear microinjection*.

Virtually any cloned DNA construct can be used, albeit some caveats apply. Linearized (as opposed to closed, circular) DNA constructs are more readily integrated into the host genome. The presence of extraneous plasmid- or vector-related DNA sequences associated with the construct can adversely affect expression of the integrated construct/transgene. Also, greater care must be taken when handling larger DNA constructs, such as those derived from yeast artificial chromosomes (YACs), to avoid damage by shearing prior to and during microinjection.

With few exceptions, microinjected constructs integrate randomly throughout the host's genome, but usually only in single locations. This fact can be exploited to obtain functional linkage of independent transgenes by simultaneous coinjection of more than one DNA construct. In such a case, both constructs tend to integrate in the same randomly located site and may exhibit coexpression. Because integration is spatially random, transgenes may be integrated into either a somatic or a sex chromosome.

The integration process itself is poorly understood, but it apparently does not involve homologous recombination. During integration, single or multiple copies (1–200) of a transgene are incorporated into the genomic DNA, predominantly as head-to-tail concatemers. Regulatory elements in the host DNA near the site of integration, and the general availability of this region for transcription, appear to play a major role in affecting the level of transgene expression. This ''positional effect'' is presumed to explain why the levels of expression of the same transgene may vary dramatically between individual founder animals as well as their offspring (or ''lines''). It is therefore prudent to examine transgene expression in offspring from at least three or four founder animals to determine what might be a result of position or incorporation site influences. Additionally, the presence of tissue- or cell-type-specific nuclear regulatory factors that act on host genes near the site of integration in cis or trans may restrict transgene expression to only a subpopulation of cells even though the transgene is present in virtually all cells of a founder.

The host DNA near the site of integration frequently undergoes various forms of sequence duplication, deletion, or rearrangement as a result of transgene incorporation. Such alterations, if sufficiently drastic, may disrupt the function of normally active host genes at the integration site, an activity that constitutes ''insertional mutagenesis,'' wherein an aberrant phenotype may result. Such events cannot be purposefully designed, but they have led to the serendipitous discovery of previously unsuspected genes and gene functions.

Because gene transfer is accomplished at the one- to two-cell stage very early in embryonic development, the transgene is incorporated into essentially every cell that contributes to development of the embryo. Thus, transgenic animals (or ''founders'') produced by this method are usually considered to be ''nonmosaic'' or ''nonchimeric,'' in the sense that the transgene is physically present in the nuclei of all cells of the body. The DNA or gene construct must be incorporated into the one-cell ovum (or a single viable blastomere) prior to DNA replication in order to appear in every descendent cell. If incorporation or integration occurs at

any later time point, then mosaicism can occur. Incorporation of the transgene into cells that will eventually contribute to development of germ cells (sperm or ova) is a common occurrence with this method, and it makes possible heritability of the transgene by offspring of founder animals. In such cases, the transgene has been said to have gone ''germ-line.'' However, integration of the microinjected DNA construct into the host's genome occasionally may be inexplicably delayed. In such a case, if cells of the early embryo (''blastomeres'') undergo mitosis before integration occurs, some but not all of the cells will contain the transgene, and the founder animal, although still considered to be transgenic, will be classified as a mosaic or chimera.

Advantages of the microinjection method are as follows: (1) the relatively high frequency of generating transgenic animals from viable microinjected embryos transferred to recipient females (20–30%), (2) the high probability of germ-line transmission of the transgene, (3) the relative lack of constraints on the size or type of DNA construct used, (4) the relative stability of the transgene as it is transmitted from generation to generation, and (5) the low frequency of mosaicism or double integrations (combined estimate of 10–30% of founders).

Disadvantages of this method include the following: (1) the random and potentially significant influence of the site of integration on transgene expression (positional effects), (2) the potential for undesired insertional mutagenesis, (3) the occasional production of mosaic founders, (4) the occasional lack of germ line incorporation, and (5) the time and expense required to obtain the skills necessary for micromanipulation and microinjection.

2.3.2 Retroviral Introduction of Transgenes

Transfer of foreign genes into animal genomes has also been accomplished using retroviruses. Although embryos can be infected with retroviruses up to midgestation, early eggs, usually at the 4- to 16-cell stages, are used for infection with one or more recombinant retroviruses containing a foreign gene. Immediately following the infection, the retrovirus produces a DNA copy of its RNA genome using the viral enzyme reverse transcriptase. Completion of this process requires the host cell to undergo the S phase of the cell cycle. Therefore, retroviruses effectively transduce only mitotically active cells. Incomplete infections, in which not all embryonic cells acquire the retrovirus, occur more frequently when using embryos after the 4-cell stage, with resultant chimeric embryos. Modifications to the retrovirus frequently consist of removal of structural genes, such as *gag*, *pol*, and *env*, which support viral particle formation. Additionally, most retroviruses and complementary lines are ecotropic in that they infect only rodents (e.g. rats, mice) and rodent cell lines rather than humans.

The DNA copy of the viral genome, or provirus, integrates randomly into the host cell genome, usually without deletions or rearrangements. However, as is the case for gene transfer by microinjection, because integration is not by way of homologous recombination, this method is not used effectively for site-directed mutagenesis.

Very high rates of gene transfer are achieved with the use of retroviruses. However, disadvantages include (1) a general limitation on the size of the foreign DNA insert that can be accommodated by individual viral strains, (2) biosafety

considerations, and potential for undesired genetic recombination that may alter the replicative characteristics of the retrovirus, (3) low copy number integration, (4) a high frequency of mosaicism (which necessitates subsequent outbreeding of founder animals to generate pure lines), and (5) possible interference by retroviral sequences on transgene expression.

2.3.3 Embryonic Stem Cell Technology

Gene transfer has been used to produce both random and targeted insertion or ablation of discrete DNA fragments into the mouse genome. For targeted insertions, where the integration of foreign genes is based on a recombinational gene insertion with a specific homology to cellular sequences (termed *homologous recombination*), the efficiency of DNA microinjection is extremely low. In contrast, the use of ES cell transfer into mouse embryos has been quite effective in allowing an investigator to preselect a specific genetic modification, via homologous recombination, at a precise chromosomal position. This preselection has led to the production of mice that (1) incorporate a novel foreign gene into their genome, (2) carry a modified endogenous gene, or (3) lack a specific endogenous gene following gene deletion or "knockout" procedures.

Technologies involving ES cells, and more recently primordial germ cells, have been used to produce a host of mouse models. Pluripotential ES cells are derived from early preimplantation embryos and maintained in culture for a sufficient period for one to perform various *in vitro* manipulations. The cells may be injected directly into the blastocoel of a host blastocyst or incubated in association with a zona-free morula. The host embryos are then transferred into intermediate hosts or surrogate females for continued development. Currently, the efficiency of chimeric mouse production results in about 30% of the live-born animals containing tissue derived from the injected stem cells. This ability to produce "chimeric" animals using ES cells has given researchers another tool in their armamentarium for the production of transgenic animals. In this set of techniques, the power of gene-transfer technology has been catapulted forward because such processes allow for targeted insertions into the genome. Such targeting is extremely important, particularly in areas of gene therapy and correction, wherein previous technologies allowed only for random integration events.

The genome of ES cells can be manipulated *in vitro* by introducing foreign genes or foreign DNA sequences by techniques including electroporation, microinjection, precipitation reactions, transfection, or retroviral insertion. The use of ES cells to produce transgenic mice faced a number of procedural obstacles before it became competitive with DNA microinjection as a standard technique in mouse modeling.

The first procedural obstacle in creating ES cell–derived transgenic animals was the extreme difficulty associated with the production and maintenance of ES cell lines. This problem lies in the general inability of embryos of most mammalian species, other than mice, to survive *in vitro*. A standard technique for producing murine ES cells involves culture of embryos *in vitro*, up to and beyond the point at which they would normally implant in the uterus. In mouse-embryo culture, this period is mimicked through coculture on fibroblast monolayers or by the inclusion of various growth factors, (leukemia inhibitory factor [LIF], ciliary neurotropic factor [CNTF], etc.) in the medium. In the case of coculture, fibroblasts serve as

a substrate for the attachment of developing embryos, enabling them to develop to a stage at which ES cells may be harvested. Additionally, although not completely understood, culture conditions and media/sera, as well as the handling of ES cells before and during transfer procedures, play critical roles in experimental efficiencies.

Following identification of true ES cells and subsequent gene-transfer procedures, it is necessary to accurately and efficiently identify ES cells that have integrated foreign DNA. In this regard, the use of marker-assisted selection schemes has greatly simplified mouse experimentation. Some genes were easily selectable *in vitro* and therefore made screening less difficult, but most were not. In these latter cases, PCR technology has been used effectively to screen for homologous recombination events. Mutated copies of normal endogenous gene sequences have been inserted in place of normal cellular sequences, and PCR techniques were used to screen for the novel mutants, with the capability of detecting even a single base-pair mutation. Hence, PCR techniques have proven to be valuable tools in selecting altered ES cell clones for use in transgenic animal production.

ES cell–chimeric animals may indeed harbor cells of both host embryo and ES cell derivation, extending the study of germ line transmission of desired transgenes to one or more additional generations, compared to most microinjection-derived transgenic animals. Concerns associated with the difficulty of line maintenance for DNA microinjection-derived transgenic animals are minimized, however, because the ES cells have the potential to give rise to multiple founder animals harboring the same transgene at the same chromosomal integration site. More recently, with the addition of coculture techniques involving tetraploid host embryos (eight-cell stage to morula), founders can be derived completely from the cocultured ES cells. Hence, the founders are no longer chimeras, having become ''better engineered'' models.

Still, for most modeling employed today, germ line transmission of transferred genes in ES cell derived mice is influenced to a great extent by the background genetics of host and donor strains of mice. Interestingly, germ line transmission is routinely problematic in some strains but not in others. The underlying biological mechanisms responsible for such differences are not known.

While putative ES cell lines have been identified for species other than the mouse, production of germ line ES cell derived/chimeric animals has proved difficult. If ES cells are identified that could give rise to germline–competent animals, it is probable that gene transfer into such cells would be successful – based on the wealth of available gene-transfer literature. Thus, the most obvious question to pose today is: Why has it been difficult to procure and utilize embryonic-derived pluripotential stem cells (ES cells) in mammalian species other than the mouse? Is it that present-day difficulties reflect an evolutionary mutation in the mouse genome, but not in other species, allowing immortalization of pluripotent cells? Or perhaps, might the idealized conditions just be beyond our immediate grasp?

2.3.4 Nuclear Transfer (Cloning) Methods

Nuclear transfer, or cloning, refers to the transfer of a nucleus from either an undifferentiated stem cell or a differentiated adult (somatic) cell to an enucleated oocyte, thereby producing a now-viable embryo. When this embryo is transferred into a

suitable female, it can develop to term and produce a live animal that is theoretically genetically identical to that from which the donor nucleus was obtained. If cloning can be done with differentiated cells from adult animals with desirable genotypic and phenotypic superiority, then many genetically identical copies can be produced as an important experimental or commercial resource.

The first cloned mice were identified in 1998 by the "Honolulu Method" of nuclear transfer using adult cells (cumulus cell nuclei). Furthermore, serial nuclear transfer resulted in cloned offspring from previously cloned animals, demonstrating conclusively that cells from cloned animals were not different from normal mice in their ability to create new clonal generations.

Embryonic stem cells, cumulus cells, cultured follicular epithelial cells, tail tip cells, fibroblast cells, neuronal cells, lymphocytes, fetal gonadal cells, Sertoli cells, as well as blastomeres up to the compacted morula stage have now been successfully used in nuclear transfer protocols. Yet surprisingly, at this time, cloning by nuclear transfer using adult donor cells has not been successful in nonhuman primates, suggestive of a comparative species-specific biological phenomenon; however, nuclear transfer was pioneered in domestic animals, and has now been demonstrated in a number of species to date.

In the Honolulu method, metaphase II oocytes are collected from the oviducts of superovulated donors and enucleated using a holding pipette to stabilize the oocyte and an enucleation pipette to aspirate the chromosome–spindle complex. A nucleus from a cumulus cell, with most of the cytoplasmic material removed, is then injected into the oocyte. Electrofusion has also been used in place of nuclear microinjection to reconstitute the embryo. Following activation, the embryos are cultured to the two-cell stage overnight and then transferred into oviducts of foster mothers.

The advantages of nuclear transfer over other techniques include the following:

- Most of the oocyte and embryo-handling procedures have already been worked out in the course of transgenic animal production.
- Because cumulus cells are relatively easily obtained and greater than 90% are in G_0/G_1 phase of the cell cycle, (no *in vitro* culturing required), cumulus cells are good nuclear donors for cloning in mice.
- Cloning of mice from ES cell nuclei combines the possibility of genetic manipulation of ES cells with cloning by nuclear transfer.

Yet, there are still a number of limitations to the current technologies. The principal concern, reported by a number of leading laboratories, is that cloning by nuclear transfer remains relatively inefficient. Well under 5% of ova and nuclear transfers with cumulus or somatic donor cells develop to term. Beyond the relative experimental efficiencies, potential reprogramming and developmental consequences of the various nuclear transfer related procedures are poorly characterized to date. Similarly, influences of epigenetic and mitochondrially encoded modifiers will undoubtedly influence potentially undesirable outcomes.

2.3.5 Other Methodologies

Today, a host of techniques have been applied to the genetic modification of mice. In the late 1960s and 1970s, blastomere or embryo aggregation and teratocarcinoma

cell transfer were used to transfer whole genomes into mouse ova. From the early 1980s, beyond DNA microinjection, retroviral infection, ES cell technologies, and nuclear transfer, we have also seen development of cytoplast and karyoplast fusions (including nuclear transfer), spermatozoa- and spermatogonial cell–mediated transfer, and particle bombardment and jet injection procedures. The later techniques expand upon earlier ''building blocks'' of genetic engineering technologies. As such, our capabilities and efficiencies will surely continue to evolve. Yet, there have been some conspicuous developments of general interest to the scientific community that may augment some of these existing methods.

Gain-of-function and loss-of-function modeling have, for the most part, concentrated on introducing specific mutations into the nuclear genome. From a gene ablation standpoint, creation of loss-of-function models will be facilitated by the emerging technology of RNA interference (RNAi). Short, interfering RNA (siRNA) exists in a double-stranded state and inhibits endogenous genes (and/or exogenous sequences as in viral genes) due to a complementary sequence homology. RNAi technology has potential applications including the inhibition of viral gene transcription and inhibition of endogenous genes coding for deleterious gene products. Indeed, germ line competent transgenic mouse and rat models using RNA interference have been shown to recapitulate null phenotypes.

In contrast to various methods to target modification of the nuclear genome, little attention was focused until recently, on the importance of mitochondrial genetics and the mitochondrial genome in mammalian development. This omission, in part, is related to the difficulty associated with *in vivo* mitochondrial transfer. Without an approach in hand, a significant technological hurdle remained in the identification of mitochondrial gene targets appropriate for engineering or modification. For a host of applications, the ability to manipulate the mitochondrial genome and to regulate mitochondrial gene function would provide an additional target in modifying mammalian development.

We and others have initiated studies revolving around mitochondrial transfer and techniques to produce animals harboring foreign mitochondrial genomes. The creation of transmitochondrial animals represents a new model system that will provide a greater understanding of mitochondrial dynamics, leading to the development of genetically engineered production animals as well as therapeutic strategies for human metabolic diseases affected by mitochondrial mutation or function.

2.4 Other Laboratory Animal Models

Transgenic animal protocols developed in mice have been modified to accommodate production of other transgenic species. In particular, the larger body sizes of rats and rabbits, their short estrous cycles and gestation lengths, their relatively rapid generation times, and their litter-bearing ability have helped make these animals preferred models for several areas of research employing gene transfer. As with mice, DNA microinjection has been the method used most frequently for introduction of foreign DNA. Differences between these species and mice in the size of ova, physical response to microinjection, requirements for *in vitro* ova culture, and numbers of fertilized eggs needed for embryo transfer (to maintain pregnancy), as well as differences in general husbandry

practices are well documented and used to optimize production of transgenic rats and rabbits.

In some cases, specific physiological characteristics unique to a species have made it a more appropriate or successful model for a particular disease; such was the case for lines of transgenic rats exhibiting hypertension-induced symptoms and pathology resulting from overexpression of specific transgenes (viz. a mouse *Ren*-2 renin transgene or a human angiotensinogen gene construct) that were not similarly expressed in transgenic mice.

Both transgenic rats and rabbits have provided models for the study of specific cancers: transgenic rats expressing an SV-40 T-antigen construct controlled by an albumin promoter develop hepatocellular carcinomas. Transgenic rabbits in which expression of a c-*myc* transgene construct is driven by a rabbit immunoglobulin enhancer exhibit malignant lymphocytic leukemia. Particular strains of rabbits have historically served as models for the study of lipid and lipoprotein metabolism. In this tradition, lines of transgenic rabbits bearing human apolipoprotein A-I antisense transgenes have been generated for the study of the biosynthesis of high density lipoproteins.

Finally, several studies have proven rabbits to be acceptable models for ''gene pharming.'' In these experiments, foreign proteins are expressed in transgenic animals, preferentially in mammary tissue, and are secreted into milk, from which they can be readily purified. Rabbits are considered to be suitable models for such use for three reasons: lactating females produce relatively large volumes of milk daily, rabbit milk possesses a high protein concentration, and they tend to nurse their offspring infrequently. To date, transgenic rabbits have been separately produced, in which human proteins (e.g. α_1-antitrypsin, interleukin 2, growth hormone, tissue plasminogen activator) and bovine α-lactalbumin have been expressed in mammary tissue and harvested from milk.

3 Production of Transgenic Domestic Animals

3.1 Overview

The success of transgenic mouse experiments led a number of research groups to study the transfer of similar gene constructs into the germ line of domestic animal species. These efforts have focused on addressing one of the three research goals: improving the productivity traits of domestic food animal species, development of transgenic animals for use as bioreactors (i.e. producers of recoverable quantities of medically or biologically important proteins), and in developing tissues, organs, or reagents for transplantation-related endpoints. Toward these goals, a number of strategies have been employed to date. Such strategies run the gamut from molecular modeling (systems designed to study dominant gene expression, homologous recombination/gene targeting and the use of ES cells) to cell biology (efficiency of transformation of eggs or cells) to blocking or ablating gene function (disruption of gene expression by antisense or RNAi transgene constructs, gene ablation or knockout models). Since 1985, numerous studies have focused on transgenic farm animals created using growth-related gene constructs. Unfortunately, for the most part, deleterious consequences of various manipulations have failed to identify commercially useful animals because of an inability to coordinately regulate

gene expression – in deference to the ensuing cascade of endocrine events that unfolded. In contrast, efforts at using domestic farm animals as bioreactors or in transplantation-related efforts have continued to progress, and viable products are expected to petition for regulatory approval shortly. Whether they will gain market acceptance is still largely unknown.

3.2 Methodology

Today, DNA microinjection, retroviral transfection, nuclear transfer and passive transfer procedures (e.g. sperm-mediated transfer) have been used to successfully produce transgenic livestock. Genetic-engineering capabilities will continue to mature, in concert with advances in whole-animal and somatic-cell techniques (including liposome-mediated gene transfer, jet injection, and particle bombardment). Envisioned progress and expansion of our existing knowledge base will allow us to better maximize and engineer production traits in farm animals in a most effective fashion.

Along the same lines, procedures to augment gene-transfer efficiencies have a high priority, especially where long gestational intervals prove problematic. Protocols have been developed to permit removal and screening of individual blastomeres from preimplantation embryos maintained in culture prior to transfer to recipient females. Sensitive methods involving the use of conventional and real-time PCR allow analysis of DNA purified from individual blastomeres and subsequent identification of those embryos that bear genetic modifications of interest. Use of such methods offers the potential to greatly increase the efficiency associated with production and selection of transgenic farm animals and to thereby significantly reduce the associated costs.

3.2.1 DNA Microinjection

DNA microinjection was the first method used to successfully produce transgenic livestock. Although involved and at times quite tedious, the steps in the development of transgenic models are relatively straightforward. Once a specific gene sequence is cloned and characterized, sufficient quantities are isolated, purified, and tested in cell culture. If *in vitro* mRNA expression of the gene is identified, the appropriate fragment is linearized, purified, and readied for preliminary mammalian gene-transfer experiments. The DNA microinjection experiments are first performed in the mouse model. While the transgenic mouse model will not identify likely phenotypic expression patterns in domestic animals, we have not observed a single construct that would function in a pig when there was no evidence of transgene expression in mice. Therefore, preliminary *in vitro* and/or *in vivo* experimentation has been a crucial component of any gene-transfer experiment in domestic animals.

Following confirmation of transgene expression in mice, it then becomes cost-effective to initiate DNA microinjection experiments in other species. In mouse experiments, less than two months is required from the time the purified construct is ready for microinjection through weaning of founder pups. In contrast, for pig experiments, one month to a year is required for a sufficient number of DNA injections and recipient transfers to ensure the likelihood of success. Experimental efficiencies coupled with a long generational interval (i.e. 114 day gestation period, 21–28 day lactation, and onset of puberty between 6–9 months of age), reflect the efforts necessary to

identify and characterize transgenic pigs and illustrate the extended time lines associated with the production of any transgenic livestock model. In addition, the time frame from birth of pigs or cattle to the establishment of lines can be 1–2 years to 4–5 years respectively (while also dependent on the sex of founders). Hence, there is an obvious advantage to characterizing transgenic mouse models to expedite what will ultimately be a lengthy undertaking.

3.2.2 Retroviral Infection

Retroviruses have been used as vectors for transfer of foreign genes into domestic animal genomes, and are particularly exciting because of the promise of 100% transfer efficiency. Although embryos can be infected with retroviruses up to midgestation, early eggs, from oocytes to 16-cell stage ova, are used for infection with one or more recombinant retroviruses containing a foreign gene. Immediately following infection, the retrovirus produces a DNA copy of its RNA genome using the viral enzyme, reverse transcriptase. Completion of this process requires that the host cell undergoes the S-phase of the cell cycle. Therefore, retroviruses effectively transduce only mitotically active cells. Modifications to the retrovirus frequently consist of removal of structural genes, such as *gag, pol*, and *env*, which support viral particle formation. Additionally, most retroviruses and complementary lines are ecotropic in that they infect species-specific cell lines, limiting risk to humans in animal experimentation.

Advantages of retrovirus-mediated gene transfer include the technical ease and efficiency of existing methods. Very high rates of gene-transfer are achieved with the use of retroviruses, thus, minimizing the numbers of ova and animals needed for gene-transfer studies. Additionally, integration of viral genes does not appear to induce genetic rearrangements of the host genome (occasionally reported with other methods), with the exception of a possible short duplication at the site of integration.

However, of the disadvantages listed in Sect. 2, the first two limitations appear to raise the greatest concern at this time. From a size perspective, the maximum permissible size for efficient encapsidation or reverse transcription of each retroviral vector is approximately 10 kb. Because introns of foreign genes carried by retrovirus vectors are spliced out during replication, the insert does not have to contain introns, yet, intronic sequences can be critical for optimal gene expression and regulation. From a biosafety perspective, disabled retroviruses may become replication-competent via potential recombination events that may occur between or within retroviral vector, packaging cell lines, and the host genome. Biocontainment and safety considerations are still debated. Yet, work to date has illustrated and further characterized the utility of sensitive analytical methods to detect unexpected viral transmission and recombination risks. In addition to legislative and regulatory oversight, conscientious mechanisms now in place help ensure that proper methods and safeguards are incorporated into ongoing experimentation.

3.2.3 Nuclear Transfer

Cloning is generally associated with nuclear transfer whereby a nucleus provided by a donor cell is introduced into an enucleated oocyte (unfertilized ovum) or zygote allowing for reprogramming of the developing embryo. It should be noted that nuclear transfer, with nuclei obtained from either mammalian stem cells or differentiated adult cells, is an especially important

development in species beyond the mouse model. This is because a technological barrier was surpassed that allowed for specific *in vitro* manipulations that lead to targeted genetic modifications in first-generation founder animals. Prior to the mid-1990s, it was not possible to produce germ line–competent transgenics in mammalian species other than in mice, using any technique other than DNA microinjection (that only allowed for random and imprecise integration of transgenes in founder animals). Unfortunately, relative efficiencies for nuclear transfer experimentation still pales in comparison to conventional DNA microinjection. However, while nuclear transfer might be considered inefficient in its current form, major strides in enhancing experimental protocols within the next few years are envisioned, comparable perhaps to the early advances in DNA microinjection technology.

Nuclear transfer involves a technique in which nuclei of various cell origins are introduced as noted in Sect. 2 above (Fig. 2). The successful ''cloning'' of a sheep was reported in the mid-1990s and rekindled the imagination of researchers struggling with microinjection and related technologies. Yet, while nuclear transfer might be considered inefficient in its current form, major strides in enhancing experimental protocols have been envisioned, and with recent *in vitro* maturation of pluripotential cell lineages, the marriage of a number of existing techniques may prove fruitful in the near term.

The techniques for nuclear transfer in domestic animals mirror what is currently employed for mouse studies. Nuclei from quiescent (G_0) cells (or the intact

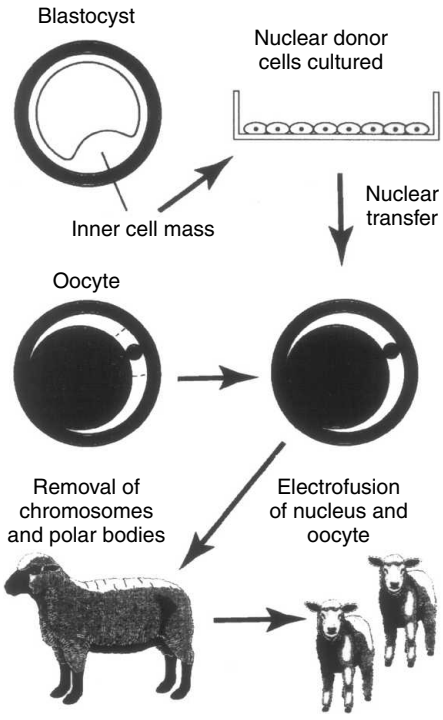

Fig. 2 Cloning sheep by nuclear transfer. In this example, inner cell mass cells from blastocyst stage embryos (or cells from somatic tissues) are obtained and propagated in culture. If so desired, the culture capability here, allows one to genetically modify cells prior to transfer. Selected cells are then used as nuclear donors for transfer into enucleated oocytes. In contrast to DNA microinjection, a fusion step is generally employed to fuse the transferred nuclei and enucleated oocytes. Here, electrofusion is used to fuse couplets (a donated nucleus plus enucleated oocyte) that are then transferred to recipients for the remainder of gestation. (Reprinted from Pinkert, C.A., (2000) *Reproduction in Farm Animal*s, 7th ed., Hafez, E.S.E. and Hafez, B., Eds., Williams & Wilkins, Baltimore, Chap. 21, pp. 318–330. With permission.)

cells themselves) can be transferred by electrofusion, polyethylene glycol-induced fusion, or by direct injection into enucleated metaphase II oocytes. Following culture, the reconstituted embryos are transferred to the reproductive tracts of host animals. Since *in vitro* culture of reconstituted sheep embryos is relatively inefficient, they can instead be transferred to an intermediate (temporary) host. After *in vivo* incubation, they can be recovered and transferred to the final host to develop to term.

If cloning can be done with differentiated cells from adult animals with proven phenotype/genotype superiority, then many genetically characterized clones can be produced as an important experimental/commercial resource (particularly for the requisite "between batch" consistency needed for biomedical reagent production). However, there are still a number of procedural hurdles to reduce the costs associated with nuclear transfer – extending the overall utility of the methodology. With both sheep and cattle, there has been a very low success rate with a high percentage of fetal loss. With sheep, especially using adult donor cells, there is a significant loss of embryos, fetuses, and newborns and the process is very inefficient. Only 10–50% of nuclear-transferred embryos develop to the blastocyst stage, independent of *in vitro* or *in vivo* developmental concerns and again, there is less than a 5% yield in total live offspring (on the basis of embryos needed to generate founder animals). Lastly, the developmental consequences of nuclear transfer procedures are still controversial, with issues regarding birth weight of cloned animals, premature aging phenomena, and relative health and immunocompetence coming under significant scrutiny as various animal models entertain commercialization prospects.

3.3 Traits Affecting Domestic Animal Productivity

Interest in modifying traits that determine productivity of domestic animals was greatly stimulated by early experiments conducted by Ralph Brinster, Richard Palmiter, and their colleagues, in which body size and growth rates were dramatically affected in transgenic mice expressing growth hormone transgenes driven by a metallothionein (MT) enhancer/promoter. From that starting point, similar attempts followed in swine and sheep studies to enhance growth by introduction of various growth hormone (GH) gene constructs under control of a number of different regulatory promoters. Use of these constructs was intended to allow for tight regulation of individual transgene expression by dietary supplementation. However, although resulting phenotypes included altered fat composition, feed efficiency, rate of gain, and lean/fat body composition, they were accompanied by undesirable side effects (e.g. joint pathology, skeletal abnormalities, increased metabolic rate, gastric ulcers, infertility). Such problems were attributed to chronic overexpression or aberrant expression of the growth-related transgenes and could be mimicked, in several cases, in normal animals by long-term treatment with elevated doses of GH.

Subsequent efforts to genetically alter growth rates and patterns have included production of transgenic livestock harboring a vast array of genes – from growth-related transgenes to immune system modulators. Other productivity traits that are major targets for genetic engineering include altering the properties or proportions of caseins, lactose, or butterfat in milk of transgenic cattle and goats, more

efficient wool production, and enhanced resistance to viral and bacterial diseases (including development of ''constitutive immunity'' or germ line transmission of specific, rearranged antibody genes). Cumulatively, it has become apparent from these studies that greater knowledge of the biology of animal development will be required before lines of domestic animals with these desired characteristics can be genetically engineered.

3.4 Domestic Animals as Bioreactors

The second general area of interest has been the development of lines of transgenic domestic animals for use as bioreactors. One of the main targets of these so-called gene pharming efforts has involved attempts to direct expression of transgenes encoding biologically active human proteins. In such a strategy, the goal is to recover from serum or from the milk of lactating females large quantities of functional proteins that have therapeutic value. To date, expression of foreign genes encoding α_1-antitrypsin, tissue plasminogen activator, clotting factor IX, and protein C were successfully targeted to the mammary glands of goats, sheep, cattle, and/or swine.

Targeting expression of the cystic fibrosis transmembrane conductance regulator (CFTR) gene to the mammary epithelium, in which the protein becomes associated with the apical membranes of these cells, has resulted in apocrine secretion of the CFTR protein as a constituent of the milk fat globule membrane. The demonstrated utility of such a targeting strategy has led to proposals for largescale production and harvesting from milk of other classes of important membrane-associated proteins, such as hormone receptors, channel proteins, and transport proteins.

Similarly, lines of transgenic swine and mice have been created, which produce human hemoglobin or specific circulating immunoglobulins. The ultimate goal of these efforts is to harvest proteins, from the serum of transgenic animals, for use as important constituents of blood transfusion substitutes, or for use in diagnostic testing.

3.5 Examples from Domestic and Miniature Pigs

In contrast to gene transfer in mice, the efficiency associated with the production of transgenic livestock, including swine, is quite low. However, two advantages offered by swine over other domestic species include a favorable response to hormonal superovulation protocols (20–30 ova can be collected on average) and a significant uterine capacity, in that swine are a litter-bearing species. The highest transgenic success rate in domestic animals has been with outbred domestic pigs, while use of inbred strains was reported to have lower overall efficiency. Since the description in 1985 of the first transgenic livestock species, DNA microinjection has to had been the only successful method identified to produce germ line competent transgenic livestock prior to nuclear transfer.

An initial problem encountered during the creation of transgenic farm animal species concerned the visualization of the pronuclei or nuclei within the ova. In lipid-dense swine ova, for example, the cytoplasm is opaque and the nuclear structures are not discernible without some type of manipulation. This was a critical problem to overcome because transgenic pigs were not produced following injection

of DNA into the cytoplasm of one- and two-cell ova. Fortunately, it was found that centrifugation of pig ova resulted in stratification of the cytoplasm, rendering pronuclei and nuclei visible under differential interference contrast or Nomarski/Smith microscopy. Even though the situation was greatly improved, centrifugation failed to reveal the nuclear structures in 15–33% of fertilized eggs. However, when using conditions initially optimized for transgenic mouse production, DNA microinjection into pronuclei/nuclei resulted in nearly a 10% yield of transgenic offspring (vs. total live-born/viable offspring).

The proportion of transgenic swine that develop from microinjected ova, which varies from zero to about 12%, is generally much lower than that observed in mice. The survival of microinjected pig embryos is related to several factors including the developmental stage of ova injected, the duration of *in vitro* culture, synchrony of ova donors and recipients, the number of ova transferred, and donor age. Other factors that have been shown to influence the developmental efficiency of transgenic mouse production – including technician proficiency and embryo handling/transfer, pipette dimensions, DNA preparation, and the viability of microinjected ova – readily influence transgenic production efficiency for all other species.

If a foreign gene fragment is integrated into a domestic animal's genome, the gene copy number and orientation (head-to-head vs. head-to-tail arrays) vary considerably, as might be anticipated from the mouse studies. In addition, mosaic animals are sometimes produced, making analysis of transgene integration more difficult. Recently, the results of PCR analyses of founder animals were useful in detecting extreme mosaicism, where a given transgene is found in only a proportion of the animal cells. While the identification of transgenic founders (both mosaic and nonmosaic) can be enhanced using PCR analyses, confirmatory DNA slot-blot or Southern blot analyses are necessary to avoid extreme and costly breeding efforts to identify germ line transmission of the transgene.

In one set of experiments, approximately 70% of pigs harboring a growth hormone gene construct (as determined by Southern blot analysis) expressed the transgene-encoded growth hormone. Failure of the remaining 30% of transgenic swine to express the foreign gene was attributed to integration of the transgene into an inactive chromosomal locus or alteration of the transgene sequence during its integration. Of the pigs that did express the transgene, the level of expression appeared to vary greatly among individuals. While cis- and trans-acting factors are obviously important influences affecting transgene expression, the integration site of the transgene is equally critical. Transgene transcription rates are likely influenced by the level of activity present at the locus, or the site of integration, and the properties of enhancer sequences located in genes flanking the transgene.

While it is not unreasonable for an investigator to suggest that 40 transgenic mice can be produced in a week's worth of DNA microinjections, there are significant differences in undertaking pig experiments. In the pioneering collaboration of the University of Pennsylvania, the University of Washington, and the United States Department of Agriculture, which first reported on the production of transgenic pigs, more than four years went into amassing the experimental results that culminated in the production of 40 founder transgenic pigs. The 55% of founder animals that expressed transgene-encoded mRNA was

very much in line with results reported by other groups.

Currently, estimates for the cost of production for each transgenic pig run from $25 000 to $125 000 (U.S.$), with the broad range reflecting the low overall experimental efficiency. The costs are compounded (doubled or even tripled) if functional transgenes and pig survival are factored into the cost estimates. To address the efficiency of the gene-transfer experiments, a modified scheduling can be employed to decrease some of the fixed and variable costs, particularly in the use and scheduling of research animals. By overlapping days of experimentation rather than synchronizing one group of donor animals per week, actual experimental costs can be reduced by more than 25%. Superovulation can induce an average of 25–30 embryos per sow. While cost-effectiveness dictates the specific regimen, all pigs do not respond similarly, and only 60% respond within a specific window of opportunity for embryo collection. This low response rate may appear unacceptable, but it should be noted that the actual yield of suitable embryos is still higher than might be available using naturally synchronized females or other superovulatory schemes.

Surgical transfer of microinjected embryos usually follows the microinjection efforts. The mechanical insult to the embryos is severe, however, and only 15–25% of them will still be viable 5 days after transfer. Therefore, 30–50 microinjected embryos are routinely transferred per recipient sow, with the expectation that 50% of the recipient females will maintain pregnancy. While the number of embryos transferred may seem excessive, the basis is derived from classical studies that establish a requirement of four viable embryos at the time of implantation for a sow to initiate and maintain successful pregnancy.

For transgene expression studies targeting pigs, the use of outbred domestic pigs is the most practical way to produce and evaluate potential models. However, miniature or laboratory swine are now used with increasing frequency in biomedical research in which desirable, well-characterized background genetics make these animals more suitable for human modeling studies (e.g. xenotransplantation research). While miniature swine are commercially available, research in developing methodologies to explore or enhance reproductive performance has been limited. Reproductive efficiency in miniature swine is low compared to commercial swine and is characterized by a low ovulation rate, low birth weight, and small litter size. In addition, extensive management is required to maintain neonates. Average litter size is between 4 and 7 pigs at birth, with each breeding sow producing 12 to 18 pigs per year. Estrous cycles and gestation length are similar to standard commercial swine; however, sexual maturity in males and females occurs between 4 and 6 months of age in some breeds, which is sooner than the 6- to 9-month norm of commercial swine.

It is important to evaluate the potential breed differences and ultimate production efficiencies using a superovulatory protocol on groups of donor animals, to be able to assess and possibly enhance the reproductive performance prior to embarking on a gene-transfer program. Trials were conducted using Yucatan miniature pigs to ascertain the feasibility of a superovulation regimen, artificial insemination, and embryo transfer to standard commercial crossbred females. Yucatan semen was collected and used to successfully fertilize ova obtained by hormonal stimulation of donor females. As it happened, only 25% of the potential eggs were recoverable and

usable (fertilized one- and two-cell ova). However, fertilized ova were obtained with enhanced efficiency compared to spontaneous ovulations in both young and aged miniature pigs.

Breeding requirements for transgenic pigs are critical, and successful management calls for expertise in fields ranging from record keeping to animal husbandry. With a gestation length of 114 days, and an interval from birth to puberty of 6–12 months, the generational interval seems extraordinarily long, particularly when one is accustomed to the experimental progress observed in mouse studies. For xenotransplantation studies, the desire to breed animals to homozygosity for the transgene poses additional challenges. Breeding schemes have been reported for production efforts that, even under ideal circumstances, lead to a three- to five-year timetable (after founders have been produced and identified), assuming no lethality associated with transgene integration and insertional mutations. There are a number of additional questions that may arise in the breeding efforts. If transgenes interact, for example, their effects may not be cumulative; indeed, it might happen that such effects mask one another, perhaps in competition for trans-activators. Other issues involve stability of the genome as well as limiting the gene pool in intricate breeding schemes. Additionally, from a technical viewpoint, evaluation of homozygosity of low copy number or single-copy transgenic animals can be very difficult, with an additional breeding/generational cycle needed to ensure the homozygous status of a transgene in any particular animal.

In future experiments with domestic animals, the ability to utilize embryonic stem cells could represent a tremendous improvement over the microinjection protocols currently in use. The ability to "knockout" or replace endogenous genes has been an extremely valuable tool in mouse genetics and modeling. Yet, characterization and use of embryonic stem cells for gene transfer has not worked to date in any species other than the mouse. The need for such technology in domestic animal species is great, and the perseverance by the groups focused on this work is exemplary.

4
Analysis of Transgene Integration and Expression

4.1
Transgene Integration

When founder mice are three to four weeks of age, biopsies are readily performed to obtain representative tissues for analysis of transgene integration and expression. For integration analysis in mice, typically tail cuts (biopsies) are performed and the tissue is digested with proteinase K followed by DNA extraction using standard protocols. Preliminary determination of transgene integration by the PCR technique can be very useful when the target sequence, the transgene, possesses unique sequences (not endogenous to the genome of the animal). However, given the extreme sensitivity of PCR and the potential for mispriming and false positives, other more specific techniques should always be used to confirm the presence of the transgene in PCR-positive samples. These include DNA slot-blotting and Southern blot hybridization, the latter being not only more informative but also less likely to present false positive signals. Additionally, the transgene can be constructed to include a molecular "tag," a unique sequence

that is easily detected and has minimal similarity to any endogenous sequence. This strategy is especially useful when the transgene itself is similar or nearly identical to an endogenous sequence. In such cases, another strategy that may be helpful is the introduction of new restriction sites into the transgene, without perturbing function, so that restriction fragment length polymorphism (RFLP) analysis can be used to distinguish the transgene from its endogenous counterpart. Finally, in some instances phenotypic screening is possible if the expression of the transgene leads to an identifiable change in the appearance of the animal. Phenotypic screening by coinjection of a second transgene that gives rise to a specific phenotype can also be useful, since cointegration is much more likely than integration of the phenotypic marker gene alone. Later, however, the integration of the transgene of interest must be confirmed by other means.

Other concerns related to the analysis of transgene integration include determinations of copy number of the transgene per cell, orientation of tandemly arranged copies, and the presence of multiple integration sites. These questions can be addressed by Southern blot hybridization following digestion of the genomic DNA with appropriate restriction enzymes. In addition, the functionality of the transgene is an important consideration in the analysis of transgene integration. However, this aspect is usually dealt with in the analysis of transgene expression (detection of a functional mRNA transcript or protein product). Finally, the critical question of whether the transgene is integrated into the germ line of the founder animal and is heritable as a stable genetic element must be answered.

4.2 Transgene-encoded mRNA Expression

The analysis of expression of the transgene is, of course, absolutely essential in determining the utility of the transgenic animals produced. As with integration analysis, the presence or absence of similar or identical endogenous counterparts will determine, to a degree, the strategies that may be most useful. For transgenes that are unique (no endogenous counterpart) or contain some unique sequences, the strategies that can be used are more straightforward. The presence of a novel mRNA transcript or a unique protein (or enzyme activity) is more easily determined than in situations involving transcripts or protein products that are very similar to endogenous transcripts or proteins. As with integration analysis, molecular ''tags'' are also sometimes useful in that the transcripts will contain some unique identifying sequence that can be readily and unequivocally determined. Once again, care must be taken to ensure that any additions or deletions designed to aid in analysis do not interfere with expression.

Technically, the most critical step in analyzing transgene expression is the isolation of RNA. Great care must be taken to avoid contamination of RNA preparations with ribonucleases (enzymes that degrade RNA). Ribonucleases are present in significant amounts in a variety of locations from which they may gain access to samples of purified RNA (e.g. the skin surface, saliva aerosols from coughing or sneezing, and airborne dust). Once a high quality RNA preparation has been obtained from the appropriate tissue, the presence of mRNA transcripts of the transgene can be determined by RNA slot-blot hybridization. A more informative

technique, Northern blot hybridization, confirms not only the presence but also the size of the transcript of interest. The Northern blotting technique consists of electrophoresis into an agarose gel to separate the RNA molecules on the basis of size, transfer (blotting) of the RNA to a nylon or nitrocellulose membrane, and detection of the mRNA of interest by hybridizing it to a specific, radiolabeled probe, followed by autoradiography.

Additional techniques exist for determining the presence of relative levels of mRNA transcripts from transgenic animals. In the nuclease protection assay, a radiolabeled probe is allowed to hybridize to the RNA in solution, followed by nuclease digestion of unhybridized RNA. The sample is then resolved on a polyacrylamide gel, followed by autoradiography to detect the probe. This technique is very useful in determining the steady state levels of RNA in a given tissue and offers an inherently high signal-to-noise ratio. In the reverse transcription-PCR (RT-PCR) assay, the RNA of interest is transcribed into a cDNA molecule by means of a specific primer and the enzyme reverse transcriptase. A second primer is added, and a standard PCR amplification is performed.

The advantage of RT-PCR lies in its extreme sensitivity – theoretically, one mRNA molecule can be amplified to a quantity sufficient for visualization on an agarose gel after ethidium bromide staining. The drawbacks include the possibility of genomic DNA contamination, in addition to the concerns associated with standard PCR reactions (e.g. false positives, mispriming, contamination, etc.).

In the *in situ* hybridization technique, a labeled probe is hybridized to a target mRNA transcript in sections of tissue to permit the identification of individual cells containing the transcript. This technique is particularly useful in identifying subsets of positive cells within a given tissue in which the relative levels of specific transcript for the tissue as a whole might be too low to be detectable by other means.

4.3 Protein Expression

In addition to the foregoing assays for transcription of the transgene, various other techniques to determine the translation of the transcript into a protein product are often employed. Most of these depend on the availability of specific antibodies to the protein of interest. The immunoblotting technique, in which proteins are resolved on a polyacrylamide gel, transferred to a membrane, and detected by means of a labeled antibody, is useful in verifying the appropriate molecular weight of the protein product of interest. Although rarely used, the radioimmunoprecipitation assay can also serve in the determination of the size of the protein product and to allow for various other manipulations, including peptide mapping and isoelectric focusing, to verify proper modification of the protein. To identify the cells within a tissue that contain the protein product of the transgene, immunohistochemical ''staining'' of tissue sections with a labeled antibody is often employed.

Some experiments involving transgenic animal production focus on measuring the influence of various cis-regulating DNA sequences; the transcript and ultimate protein product are for the most part irrelevant. In these cases, ''reporter genes'' are often employed because they can simplify determination of expression levels by producing a transcript or protein that is easily and unequivocally detectable. Particularly useful in these applications are reporter genes that code for novel enzymes

in that the activities of the enzymes can be assayed, thus greatly increasing the sensitivity of detection.

In analyzing the expression of any transgene, it is always important to evaluate at least two separate lines of transgenic animals, to show that the expression patterns are consistent and reproducible. It is not uncommon for the site of integration within a given line of transgenic animals to have profound influence on transgene expression, independent of any transcriptional control sequences in the transgene itself.

5
Conclusions and Future Directions

5.1
Gene Transfer Today

The efforts and costs for gene-transfer experimentation in animal biology are challenging and limiting. Innovative technologies to enhance experimental gene-transfer efficiency in different species are desperately needed. Such enabling techniques would not only bring the cost of individual projects into a reasonable realm but would also increase the likelihood of breakthrough studies in many disciplines. As stated earlier, aside from mouse modeling, DNA microinjection into preimplantation embryos has been the only reproducible means for heritable gene transfer in the preponderance of mammalian species, other than multigene-targeted (nonspecific) blastomere aggregation and nuclear transplantation studies.

The outlined efficiencies for the production of transgenic animals represent what is considered to be current ''state-of-the-art'' technology. It is envisioned that procedures will be modified and enhanced as new research efforts are reported. Under the circumstances, there are a number of specific achievements that would significantly enhance experimental productivity. Enabling technologies would center on the following areas:

- development of alternate DNA delivery systems (e.g. embryonic stem cell transfer for stable gene transfer, liposome-mediated gene transfer, or perhaps targeted somatic-cell techniques);
- the identification of optimal experimental conditions for a given form of gene transfer and the identification of animal strains best suited to the individual technologies;
- complete animal genome mapping and identification of homologies to human genes;
- the establishment of routine and efficient embryo and germ plasm culture systems;
- the development of a means to reduce the number of animals and embryos required (e.g. use of PCR amplification of blastomere DNA or fluorescence-activated cell sorter (FACS) analyses and gating of transfected germ plasm);
- enhancement of relative experimental efficiencies to minimize the numbers of animals, gametes, and related reagents necessary to generate founder animals or experimental models.

Primary considerations for genetic manipulations and gene transfer are not limited to donor and recipient requirements, surgical manipulations, embryo handling, and gene-transfer skills, but also include expertise in tissue/cell culture and molecular biological techniques. For any animal experimentation, ethical considerations, regulatory requirements,

and experimental design are also important considerations that may limit research efforts. For most species, husbandry considerations are extensive in comparison to mouse requirements, running the gamut from animal and record-keeping management to female- (e.g. controlled estrus cycles/synchronization) and male-specific (e.g. sperm analysis/quantitation) requirements. For most nonrodent species, procurement of embryos and the trauma associated with most manipulations are significant factors. The refinement of nonsurgical techniques for embryo collection and transfer would bypass a huge financial and labor requirement for many large domestic animal species. More importantly, experimental animals would no longer be necessarily subjected to significant surgical manipulations. Perhaps recent advances, involving embryo aggregation and the derivation of transgenic mice completely from early passage ES cells, may shed new light on novel and efficient techniques.

5.2 Future Directions

For many species, there are technical drawbacks to various genetic-engineering technologies that are manifest in the lack of significant gene characterization and mapping efforts. With the complexity of the mammalian genome, this information is critical for the determination of appropriate genes to engineer and transfer, and in providing preliminary indications of the potential biological consequences of genetic-engineering experimentation. What are the appropriate genetic targets in different species and how will gene-targeting manipulations influence mammalian development? If genetic polymorphisms (indicative of related genes that code for different isoform proteins) or pseudogenes are present, targeting efforts can be long and arduous. For well-characterized genomes, the identification of specific genetic variations or deficiencies may provide only a glimpse of the effort necessary to develop in other species. Yet, it is hoped that with current efforts focused on the human and animal/species-specific genomes, accumulating data will prove quite informative and adaptable, inasmuch as conserved linkage groups are highly probable and would be exploitable.

While current experimental efficiencies for transgenic animal production are relatively poor, the mechanical aspects of producing transgenic animals should not overshadow our ability to create and evaluate biologically important animal models. Much has been learned about early development and effects of altering the growth cascade as well as other physiological processes in initial transgenic animal models. These models have had far-reaching effects and have redefined what is possible in the biological, biomedical, and agricultural sectors. While studies of transgene expression and overexpression in mammalian models may not always correlate exactly, nor reveal all the possible effects and consequences when extended to human biology, the utility of transgenic animal models to scientific discovery cannot be overestimated. The use of ES cell or related methodologies to provide efficient and targeted *in vivo* genetic manipulations offers the prospects of creating profoundly useful animal models for biomedical, biological, and agricultural applications. However, the road to such success will continue to be most challenging.

Keywords

Exocytosis
Release of secretory product from a cell by fusion of an intracellular vesicle containing the product with the cell-surface membrane.

Membrane Fusion
Merger of two biological membranes to form a single membrane, as when the membrane of a secretory vesicle fuses with the surface membrane of the cell.

Phospholipid
Common constituent of biological membranes composed of two fatty acids esterified to a glycerol backbone with a head group containing a phosphate ester.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Edited by Robert A. Meyers.

Phosphorylation
Covalent attachment of phosphate, as in the enzyme-catalyzed phosphorylation of serine or tyrosine amino acid side chains in a protein.

The annexins are a family of structurally related, calcium-dependent, phospholipid-binding proteins that have been postulated to mediate calcium-dependent activities at membrane surfaces such as membrane fusion, lipid metabolism and reorganization, and ion permeation. The basic annexin structure consists of 4 homologous 70–amino acid repeats and a unique N-terminal domain. These repeats do not contain sequences found in other intracellular calcium-binding proteins; therefore, the annexins represent a novel class of calcium-binding proteins. The ''core'' domains of all the annexins, composed of the four 70–amino acid repeats, are 40 to 60% identical in sequence. One annexin family member (annexin VI) has been formed as a result of gene duplication and consists of 8 of the 70–amino acid repeats. Another type of duplication has occurred with annexin II (calpactin), in which two 36-kDa molecules, the ''heavy chains,'' each containing four repeats, bind to a dimer of a 10-kDa protein, the ''light chains,'' to form a tetramer. In contrast to other lipid-binding proteins such as protein kinase C, or phospholipase A2, the annexins are unique in that most are bivalent. That is, they can attach to two membranes, rather than just one, and as a consequence, draw them together.

1 Diversity and Functions

Members of the annexin family of proteins, of which there are now 11 recognized mammalian variants, have been independently discovered in a number of contexts. As a consequence, a variety of names have been used for the different family members, such as *synexins, chromobindins, lipocortins, calcimedins, calphobindins,* and *calpactins*. However, a standard reference nomenclature has been adopted involving the term *annexin* followed by a Roman numeral (Fig. 1). Representative annexins have been isolated from animals, plants, and the slime mold *Dictyostelium,* attesting to the universality of the functions performed by annexins. Owing to the bivalent activity of the annexins, one of their postulated roles is the promotion of membrane fusion in exocytosis. After secretory vesicle membranes have been aggregated by an annexin, they undergo fusion if exposed to cis-unsaturated fatty acids. In a cell, such fusogenic fatty acids might be made available through activation of lipases. Alternatively, the annexins might function in concert with other proteins that promote membrane fusion and remodeling after the membranes have been brought into close apposition by the annexin. In addition to a possible role in exocytosis and membrane trafficking, some of the annexins have been suggested to be mediators of the anti-inflammatory effects of steroids, components of the submembranous cytoskeleton, inhibitors

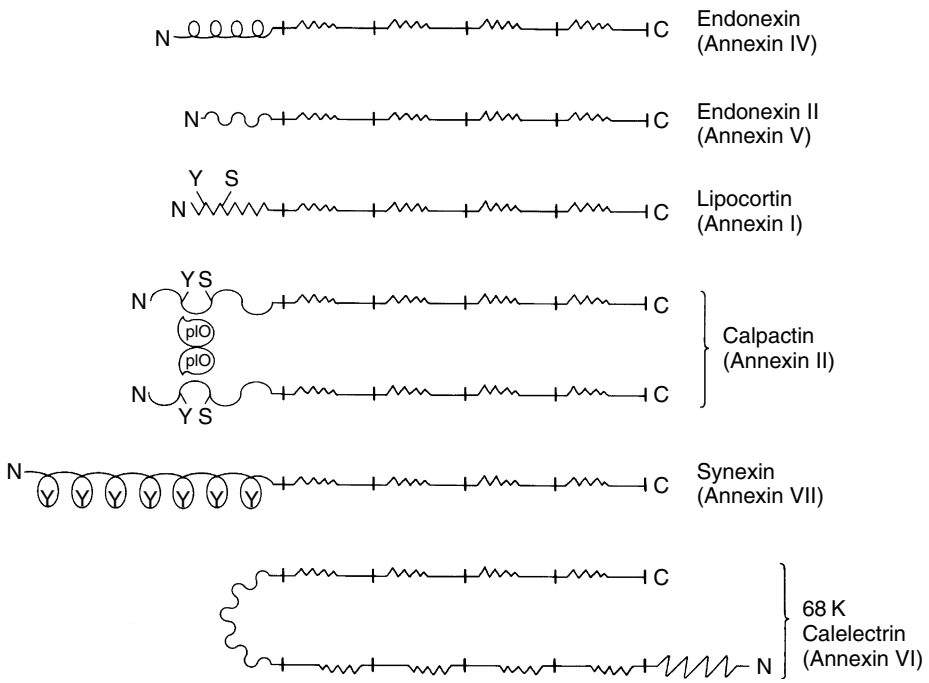

Fig. 1 Schematic illustration of the primary structures of six annexins. Each of the 4 (or 8) homologous domains contains the 17–amino acid "endonexin fold" sequence represented by a sawtooth line (sequence: KGhGTDExxLIpILApR: h, hydrophobic residue; p, polar residue; x, variable residue). The unique N-terminal structures are on the left (or right in the case of annexin VI); Y and S represent phosphorylation sites in the tails of annexins I and II. The annexin II tetramer is drawn showing the association of the N-termini of the heavy chains with the light-chain (p10) dimer. The *Y*s inside the loops in the tail of synexin represent a pro-β-helix. [Reproduced from Dedman and Smith (1990), with permission.]

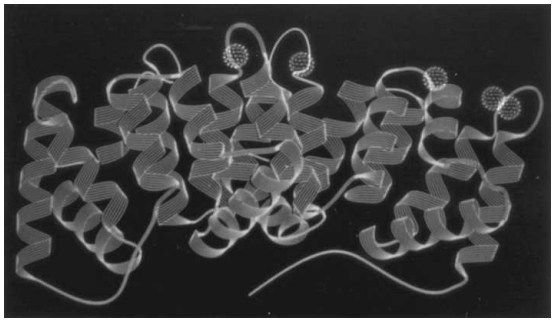
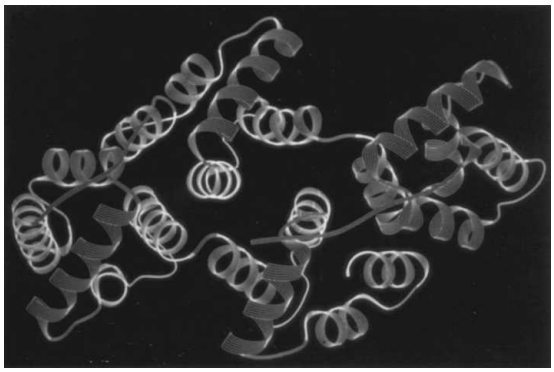
of blood coagulation, transducers of signals generated by tyrosine kinases at the cell membrane, mediators of bone formation and remodeling, mediators of cell-matrix interactions, voltage-dependent ion channels, actin bundling proteins, regulators of calcium release channels in muscle, regulators of DNA polymerase activity, and extracellular binding sites for plasminogen. This diversity of hypotheses attests to the ubiquitous and abundant nature of these proteins. In most cases, the data supporting a role for the annexins in these various processes are derived from *in vitro* systems involving calcium and lipid membranes, and it has been difficult to relate these activities to true cellular functions. However, it seems likely that this family of proteins has radiated to perform a variety of cellular functions, since so many are coexpressed in single cells and their individual differences have been highly conserved during evolution. In that sense, the annexins may be similar to the other major class of calcium-binding proteins, the "EF-hand" family, which includes calmodulin and troponin C, and are responsible for a variety of nonoverlapping cellular phenomena.

2
Structure and Mechanism of Action

The annexins, in general, have proven to be relatively easy to isolate in high purity, and this advantage has led to several successful attempts to crystallize members of the family. The structure of annexin V reveals that each of the four 70–amino acid repeats forms a compact bundle of α-helices and these four bundles are arranged in a plane (Fig. 2). Viewed from the side, the molecule displays a convex face, thought to be the membrane-binding face, and a concave face, thought to face the cytoplasm. Each homologous domain forms one or two potential calcium binding sites, which are complex in that they involve convergent loops from different parts of the domain. In addition, the positions of sulfate ions in the loops (derived from the crystallization medium) suggest that the phosphate of a lipid head group may also sit in the binding pocket and coordinate the calcium ion. This geometry would explain the interdependence of calcium and lipid binding by the annexins. Since all the lipid binding sites of the annexin core domains face a single membrane, they may be able to integrate information about membrane-lipid composition. In general, all the annexins bind with higher affinity (i.e. at lower levels of calcium) to acidic phospholipids. However, there is some variation reported in the literature for different annexins with regard to order of preference for



(a)



(b)

Fig. 2 Ribbon plots of the structure of annexin V as determined by X-ray diffraction. (a) ''Side'' view of the molecule, with the calcium binding sites and the membrane-binding face at the top. Calcium ions are represented by the spheres. The high-affinity sites are represented by the first, second, and fifth spheres from left to right; the third and fourth spheres indicate low-affinity ion binding sites that were identified by lanthanide binding. The extended N-terminus is seen at the bottom. (b) View of the ''cytoplasmic'' side of the molecule and the N-terminus. The calcium binding sites are on the opposite face. Note the potential channel structure in the center of the molecule. [From Creutz (1992), with permission. Original figure kindly provided by A. Burger and R. Huber.]

different acidic lipids. In addition, the four homologous repeats may have different specificities, since the repeats are only 40 to 50% identical in sequence.

The crystal structure of annexin V has also been interpreted in terms of the ion channel–forming properties of the protein. The molecule has a hydrophilic pore perpendicular to the face of the membrane (Fig. 2). Because the molecule has no hydrophobic external surfaces, it is assumed that it cannot actually enter the bilayer in this conformation. However, it has a calculated external electrical field similar to the field strength necessary to punch a hole through a membrane by electroporation. Therefore, it has been suggested that the molecule sits on the surface of the membrane and leads to a disordered state in the lipids immediately below it. In this disordered state, the membrane conducts ions that must also pass through the hydrophilic pore in the molecule. The molecule thus provides the ion selectivity of the overall transmembrane channel. A similar mechanism of membrane permeabilization has been suggested for the action of cholera toxin.

An alternative mechanism for the ability of annexins to promote ion permeation has been proposed that involves a significant reorganization of the molecule at low pH to form a transmembrane channel. However, a crystallographic model of this proposed structure has not yet been determined. It is also not known if the channel activity that annexins exhibit *in vitro* corresponds to a specific physiological channel in cells.

Since the calcium/lipid binding sites all appear to be on one side of the annexin molecule, it is not obvious how the annexins aggregate membranes. It seems likely that a self-association of annexin molecules attached to different membranes is required for membrane aggregation (Fig. 3). The concave faces of the molecules that face the cytoplasm might interlock during this self-association event. In the case of synexin acting *in vitro* on chromaffin granules (secretory vesicles of the adrenal medulla), binding to membranes occurs at low levels of calcium (less than 10 μmol), but membrane aggregation and fusion depend on higher levels of calcium (greater than 100 μmol). The calcium dependence of granule aggregation correlates exactly with the calcium dependence of synexin self-association in the absence of membranes, suggesting a mechanism for membrane aggregation whereby membrane-bound synexin molecules undergo self-association to bring the two membranes together. If this mechanism is correct, then the ''bottleneck'' in the system is the high level of calcium needed to promote annexin self-association. The annexin II (calpactin) tetramer promotes the aggregation and fatty acid–dependent fusion of chromaffin granules at the lowest level of calcium of any annexin (approximately 1 μmol). This may occur because the tetramer represents a permanently self-associated annexin (Fig. 1). The two heavy chains might be associated through the light-chain dimer in such a way that each heavy chain can bind a different membrane and thus pull them together. Therefore, the processes of overall membrane aggregation and fusion are catalyzed by the low levels of calcium needed simply to promote membrane binding.

3 Regulation

The N-terminal domains of the annexins are the major sites of sequence divergence in the family (Fig. 1). They may be the site of interaction with other proteins, as

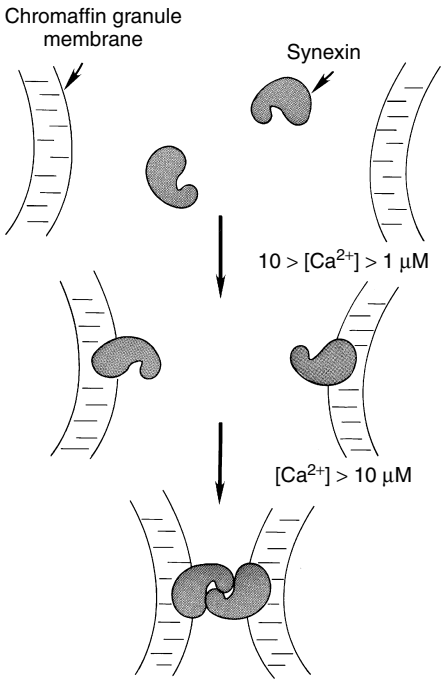


Fig. 3 Hypothesis for the mechanism of action of synexin (annexin VII) in promoting intermembrane contacts in a cell. In the resting cell (top), the Ca^{2+} concentration is less than 1 μM and synexin is freely soluble. In the stimulated cell (middle), as the calcium concentration rises to between 1 and 10 μM, synexin attaches to membranes. When the calcium concentration further increases above 10 μM (perhaps near the plasma membrane), synexin molecules on different membranes self-associate to bring the membranes together. [Reproduced from Creutz and Sterner (1983), with permission.]

in the case of the annexin II heavy chain, which associates with p10, and annexin XI, which associates with the small calcium-binding protein, calcyclin. The N-terminal domains are also potential regulatory sites for the rest of the molecule. For example, cleavage of the N-terminus of the isolated annexin II heavy chain is necessary for this protein to aggregate chromaffin granules at low levels of calcium. Furthermore, the calcium sensitivity of membrane aggregation by such cleaved molecules is strongly affected by the exact site of cleavage. In addition, annexins I and II are phosphorylated in the N-terminal domain by tyrosine- or serine-/threonine-specific kinases. Phosphorylation of the N-terminus of annexin I by protein kinase C *blocks* the ability of this protein to aggregate chromaffin granules, while slightly *enhancing* its ability to bind the granule membrane. These biochemical observations on the importance of the annexin N-terminal structure can be interpreted in terms of the crystal structure of annexin V. Since the N-terminus is located on the ''cytoplasmic'' side of the membrane-bound annexin, it may be in a position to participate in annexin–annexin self-association essential to membrane aggregation. This may explain why alterations of the tails of other annexins strongly affect membrane aggregation but not membrane binding. Such alterations, resulting from either proteolysis or phosphorylation, may provide additional mechanisms for cellular control of these calcium-dependent proteins.

4 Applications

Although the complete breadth and details of the biological roles of annexins are yet

to be determined, a number of biotechnological and medical applications are under development. Most of these applications relate to the signature ability of annexins to bind to acidic phospholipids in the presence of calcium. Members of this protein family have potential utility as anticoagulants because they can prevent the association of clotting factors with acidic lipids on the surface of activated platelets and endothelial cells. Annexins may also function as immunosuppressive agents by shielding phospholipids from attack by phospholipase A_2, thus preventing the release of arachidonic acid, which is the precursor for a number of inflammatory lipid mediators. Annexins are a staple of any research laboratory studying apoptosis *in vitro* since one hallmark of the cell death pathway is the exposure of phosphatidylserine on the cell surface, which can be marked by the binding of a fluorescent annexin. Labeled annexins have also been tested in whole animals for the ability to localize occult thromboses or apoptotic cells in whole-body imaging techniques, and annexins fused to clot-dissolving enzymes have been tested for the ability to direct these enzymes to thromboses.

Keywords

AP Endonuclease
An enzyme that cleaves apyrimidinic or apurinic sites in DNA.

Autonomous Transposable Element
A mobile element encoding enzyme(s) necessary for its proliferation in the host genome. All other mobile elements are called nonautonomous.

Consensus Sequence
A DNA or protein sequence made of nucleotides or amino acid residues prevalent at each position in a set of multiply aligned homologous sequences.

cDNA
A DNA copy of an RNA molecule created during reverse transcription.

DNA Transposon
A transposable element that moves from one genomic site to another in the form of DNA only.

Family of Repetitive Elements
Multiple DNA copies derived from a number of related transposable elements called source, founder, or master genes. A repetitive family can be divided into subfamilies, each corresponding to a separate founder gene.

Interspersed Repeats
Randomly inserted copies of currently or historically active transposable elements.

Long Interspersed Repeat (LINE) Element
A non-LTR retrotransposon encoding reverse transcriptase and endonuclease catalyzing nuclear reverse transcription and integration of cDNA in the host genome.

Long Terminal Repeats (LTRs)
200 to 3000 bp long identical DNA sequences flanking a provirus sequence.

LTR Retrotransposons
A class of retrotransposons that are reverse transcribed in the cytoplasm. The resulting cDNA is integrated into the host genome, forming a provirus flanked by long terminal repeats.

Microsatellites
DNA sequences, typically shorter than 1000 bp, composed of tandemly repeated units 1 to 10 bp long (1–6 bp or 1–13 bp ranges are also used). Microsatellites are also known as short tandem repeats (STR) or simple sequence repeats (SSRs).

Minisatellites
DNA sequences composed of tandemly repeated units longer than in microsatellites. Minisatellites span from 1 kb to 100 kb and are also known as variable number of tandem repeats (VNTRs).

Non-LTR Retrotransposons
A class of retrotransposons that are transposed via target-primed reverse transcription. Autonomous non-LTR retrotransposons encode reverse transcriptase.

Processed Pseudogene (Retropseudogene)
A pseudogene derived from usually spliced and polyandenylated host mRNA by LINE-mediated reverse transcription.

Provirus
A DNA copy of a retrovirus inserted into the genome.

Pseudogene
A nonfunctional gene copy.

Recombination
The exchange of DNA or RNA molecules.

Repetitive Elements (Repeats)
DNA fragments present in multiple copies in the genome without clearly assigned biological function.

Ribonuclease H (RNase H)
An enzyme that degrades the RNA strand of RNA–DNA hybrid molecules.

Retrotransposition (Retroposition)
A process involving transcription, processing of mRNA, translation, reverse transcription of the transcribed mRNA, and integration of the resulting cDNA into the host genome.

Retrotransposon (Retroposon)
A transposable element that is reproduced via reverse transcription of an RNA intermediate. They can be split into two classes: LTR and non-LTR retrotransposons.

Retrovirus
An RNA virus, whose life cycle includes cytoplasmic reverse transcription of the RNA transcribed from its provirus integrated into the host genome.

Reverse Transcriptase
An RNA-dependent DNA polymerase.

Satellite DNA
An array of tandemly repeated units spanning up to 10^6 bp and present mainly in centromeric and paracentromeric heterochromatin. Satellite DNA usually forms a prominent ''satellite band'' separable from the rest of genomic DNA by density gradient centrifugation.

Short Interspersed Repeat (SINE) Element
A nonautonomous non-LTR retrotransposon derived mostly from host genes containing a pol III internal promoter. SINE elements are retrotransposed by reverse transcriptase encoded by LINE elements.

Superfamily of TEs
A group of related families of transposable elements.

Tandem Repeats
DNA units arranged in a head-to-tail manner.

Target-primed Reverse Transcription (TPRT)
A mechanism of integration of non-LTR retrotransposons into the genome.

Transposable Elements (TEs, Transposons, Mobile Elements)
DNA sequences that can move to different positions in the genome either by excision and reinsertion, or by retrotransposition.

Transposase
An enzyme encoded by a DNA transposon and involved in its insertion and excision from the host DNA.

Transposition
A relocation of a DNA sequence from one genomic site to another.

Human repetitive DNA includes tandemly arrayed and interspersed repeats. Tandemly arrayed microsatellites, minisatellites, telomeric repeats, and centromeric satellites constitute a significant portion of the genomic DNA, particularly of heterochromatin. Furthermore, around 45% of the genome is represented by so-called interspersed repeats that are mostly remnants of retrovirus-like LTR retrotransposons, non-LTR retrotransposons, and DNA transposons inserted in the genomic DNA over millions of years. Currently, the most active are L1 and Alu families of non-LTR retrotransposons, and they are known to cause genetic diseases through insertion into genes. Furthermore, repetitive sequences, particularly Alu elements, can stimulate illegitimate recombinations producing chromosomal instabilities leading to genetic disorders. Analysis of repetitive DNA is an important part of genome studies, and it is based on specialized databases and computer programs.

1 Introduction

The generally synonymous terms *repetitive elements*, *repetitive* (*reiterated*) *sequences*, and *repeats* describe a broad variety of DNA sequences with copies present in multiple locations throughout the genome. They can be divided into families of similar or sometimes identical elements. This definition also covers families of genes with known functions, such as RNA genes and other multigene families. However, the subject of this chapter is limited to repetitive elements that do not have a clearly assigned biological function.

Historically, the first categorization of repetitive DNA into "highly repetitive" and "middle repetitive" was based on DNA denaturation/renaturation kinetics. This categorization refers to the physical properties of DNA that cannot be translated satisfactorily into a classification of repeats based on cloning and detailed sequence studies. In general, highly repetitive DNA primarily includes the tandemly repeated sequences described in Sect. 2, whereas the middle-repetitive DNA includes repetitive elements interspersed with single-copy DNA (Sect. 3). However, the middle-repetitive DNA may contain sequences with a very high copy number such as the Alu family described in Sect. 3.1.2.2.

On the basis of chromosomal distribution, repetitive elements are divided into *tandem repeats*, consisting of direct repetitions of the same motif, and *interspersed repeats*. Interspersed repeats are mostly inactive copies of transposable elements (TEs). Together, these elements represent around 50% of the sequenced human genome. Some abundant interspersed repeats are relatively old and diverse and cannot be clearly distinguished from "unique" DNA. This is due to the acquisition of random mutations and sequence fragmentation over time. Therefore, it is believed that the real contribution of repetitive DNA to the human genome is underestimated, and that the cited proportion of 50% only reflects the current limits of detectability.

2 Tandemly Arrayed Repeats

Tandemly arrayed repeats are composed of multiple head-to-tail repetitions of simple

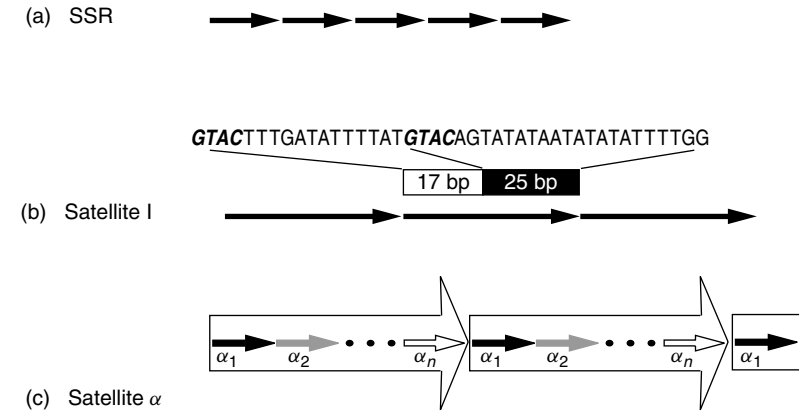

Fig. 1 Structure of human tandem repeats. (a) Schematic structure of simple sequence repeats. Arrows represent units ordered in head-to-tail fashion. (b) Structure of human classical satellite 1. Satellite 1 was originally described as a 17mer (A) and a 25mer (B) arranged in an alternating pattern A-B-A-B. This structure was inferred from the cutting of human DNA by the *RsaI* restrictase (the *RsaI* cutting sites are highlighted). Further sequence analyses revealed that satellite 1 is in fact composed of a single 42 bp-long basic unit. (c) Diagram of the hierarchical structure of human alpha satellites, showing the organization of a typical alpha satellite DNA region. Monomeric 171 bp units are represented by the small labeled arrows. The hierarchical structure of the alphoid DNA is shown by the large arrows.

sequence motifs (Fig. 1a). Human tandem repeats are composed of units ranging in size from 1 to ~1000 bp. On the basis of unit length and genomic distribution, they are somewhat arbitrarily divided into microsatellites, minisatellites, and satellites. Microsatellites are tandem arrays of short units, while minisatellites are composed of longer patterns. Micro- and minisatellites tend to be scattered all over chromosomal DNA, with some bias toward telomeric ends. The moderate degree of tandem repetition and high degree of dispersion throughout the chromosomes are the major features distinguishing micro- and minisatellites from satellites. Satellites are long, tandemly arrayed sequences located in well-defined chromosomal areas such as pericentromeric, subtelomeric, and telomeric regions. Satellites may consist of simple micro- or minisatellite-like units, but these are often organized into higher-order structures.

2.1 Microsatellites and Minisatellites

Originally, microsatellites were referred to as simple sequence repeats (SSRs) and minisatellites as variable number of tandem repeats (VNTR). Currently, the term simple sequence repeats is applied to both micro- and minisatellites. Micro- and minisatellite repeats are defined by three parameters: the *pattern* (or sequence of the unit), unit *length*, and the *number* of units.

The boundary separating micro- and minisatellites differs considerably in the scientific literature. Microsatellites are usually defined as repetition of 1–6 base pair (bp) long units, but the upper

boundary is often extended to 10–13 bp. Microsatellites are much more abundant than minisatellites.

The distribution of microsatellites in the human genome appears to be more uniform than that of minisatellites, with approximately one microsatellite for every 6 kb of DNA. Almost one-third of all potential microsatellites are simple runs of A. Such runs are often introduced as poly(A) tails of non-LTR retroposons, in particular, of Alu repeats (Sect. 3.1.2.2). Therefore, the abundance of $(A)_n$ may not be directly comparable to the abundance of other, spontaneously expanding, microsatellites. Other highly abundant microsatellites ranked in descending order are $(AC)_n$, $(AAAN)_n$, $(AAAAN)_n$, and $(AAN)_n$, including the complementary sequences. Many of these A-rich microsatellites are also spin-offs of poly(A) tails of non-LTR retroposons. Microsatellites composed of $(CAG/CTG)_n$ and $(CGG/CCG)_n$ trinucleotide repeats are less abundant, but nevertheless very important due to their connection with human diseases (Sect. 4).

The variation patterns of microsatellites and minisatellites appear to be very similar. In each case, the majority of variations are due to differences in the number of tandemly repeated units, not from mutations of the individual units. Despite the similarities between micro- and minisatellites, there are several different underlying mechanisms involved in their evolution. Indeed, the traditional division of tandem repeats into microsatellites and minisatellites is based on early hypotheses about mechanisms driving their expansion. For microsatellites, ''replication slippage'' during DNA replication was suggested, while minisatellite expansion was thought to result from unequal crossing-over. Nevertheless, our current knowledge suggests that processes driving SSR expansion are more complex and range from polymerase slippage and gap repair to DNA recombination and gene conversion. Another pathway of SSR expansion involves an initial comobilization of the microsatellite or minisatellite with transposition of another repeat, as in the case of poly(A) tails of non-LTR retrotransposons (Sect. 3.1).

Loci containing micro- or minisatellites produce a very large number of variant alleles, and the sequence length polymorphism makes micro- and minisatellites some of the most informative genomic markers. The most widely used microsatellites are the $(CA/GT)_n$ dinucleotide repeats. The variation at microsatellite loci has been used in genetic linkage analysis to establish the locations of disease genes as well as in forensics, human population genetics, and cancer genetics.

Many other kinds of simple repetitive sequences represent variable permutations of a limited number of motifs, sometimes interspersed with unique sequences. Such ''composed'' or ''cryptically simple repeats'' occur up to ten times more often in the genomic DNA than in any equivalent random sequence. They result from a systematic reshuffling of various DNA fragments differing in length and sequence composition. Therefore, they are of interest from the standpoint of genetic variability. These repeats have not yet been systematically classified or explored.

2.2 Satellites and Telomeric Repeats

Typically, satellites are arrays of 10^3–10^7 tandemly repeated units, or monomers, predominantly located in the well-defined chromosomal regions, such as centromeres and heterochromatin. Traditionally, the term *satellites* was restricted to centromere-specific repeats; however,

telomeric repeats can also be viewed as satellite-like sequences. Because of their distinct base composition, many satellites were originally discovered as a result of their separation from bulk DNA by centrifugation in buoyant density gradients. Satellites with GC content similar to that of the unique genomic DNA, which could not be separated by centrifugation, have been called *cryptic satellites*. The function of satellite DNA remains unclear. Satellites represent up to 20% of the genomic DNA, but they are underrepresented in the sequenced portion of the genome.

Table 1 lists representative human satellite sequences collected in Repbase Update (RU), the reference collection of repetitive sequences (Sect. 6.1). The most extensively studied centromere- and telomere-specific repeats are reviewed in the next two sections. In addition, there are several chromosome-specific tandem repeats, some of which are listed in Table 1.

2.2.1 Centromeric Satellites

Human centromeric DNA contains a variety of different satellite repeats. The major noncryptic satellite fractions were

Tab. 1 Human satellites and satellite-like sequences in repbase update.

Repbase	*Description*
Centromeric	
SAR	Satellite I
GAATG	Satellites II and III, both contain 5-ATTCC basic unit
HSATII	Satellite II (example, diverged copy)
ALR	Alpha satellite
ALR1	Alpha satellite subfamily 1
ALR2	Alpha satellite subfamily 2
BSR	Beta satellite
GSAT	Gamma satellite
GSATX	Gamma X satellite, X chromosome specific
CER	48-bp satellite
SN5	SN5 satellite
LSAU	Heterochromatic satellite
HSAT4	35-bp centromeric repeat
HSAT5	Centromeric repeat, 14-bp unit
GSATII	Centromere-associated repeat
D20S16	Centromere-associated repeat
Telomeric	
TAR1	Telomere-associated repeat sequence, TAR1 or SUBTEL_sat in RepeatMasker
REP522	Repetitive subtelomeric-like sequence
Others	
SATR1	Primate satellite-like sequence
SATR2	Primate satellite-like sequence
MSR1	37 bp minisatellite repeats, specific to chromosome 19, but detected in chromosome 19-derived segmental duplications located in other chromosomes
MER22	SSTI moderately repetitive family, strictly tandem repeat, appearing at 2 chromosomal locations only
ACRO1	Satellite/acromeric in all short arms of acromeric chromosomes
HSATI	Chromosome 22 satellite

defined as classical satellites I, II, III, and IV. Classical satellite I was found to be dominated by a simple component called *satellite 1*. Satellite 1 contains a 42-bp basic unit, originally described as a 17-mer (A) and a 25-mer (B), arranged in an alternating pattern: A-B-A-B (Fig. 1b). The major simple components of classical satellites II and III are named *satellites 2 and 3*, both containing the GAATG unit (sometimes described by the complementary ATTCC). Repetitive sequences from the satellite DNA fraction IV are nearly identical to those in fraction III.

Among other well-defined and extensively studied components of classical satellites II and III are the so-called *alpha satellites*, first discovered in African green monkeys and subsequently in other primates. Alpha satellite DNA is composed of a 171-bp unit (Fig. 1c). Interchromosomal sequence identities suggest that all human alpha satellites arose from two or three different ancestral monomers, which in turn diverged into 12 distinct types of alphoid monomers. They can differ by as much as 20 to 40% from one another by sequence identity.

Human chromosomes contain alpha satellites organized hierarchically into higher-order repeat arrays (Fig. 1c), which can differ between different chromosomal locations. On the basis of this organization, the alpha satellites from the human genome have been divided into five suprachromosomal families: the first family consists of alpha satellites located on chromosomes 1, 3, 5, 6, 7, 10, 12, 16, and 19; the second comprises chromosomes 2, 4, 8, 9, 13, 14, 15, 18, 20, 21, and 22; the third is located on chromosomes 1, 11, 17, and X; the fourth family is found on chromosomes 13, 14, 15, 21, 22, and Y; and, finally, the fifth family was detected on chromosomes 5, 6, 13, 14, 19, and 21.

Members of each suprachromosomal family share a common alpha satellite repeat unit. The size, conservation, and organization of these higher-order structures depend on the chromosome and on the physical distance from the centromere. Apart from the five classical suprachromosomal families, other higher-order structures have also been described. For example, the central region of the chromosome X centromere contains a specific alpha satellite array arranged into 2-kb long highly identical blocks.

The evolution of alpha satellites is complex, and is driven by intra- and interchromosomal recombination and gene conversion. The recombination occurs during chromosomal pairing and leads to an unequal crossing-over between chromosomes. As a result, stretches of alpha satellite DNA expand and contract at a very rapid rate. In addition, the alpha satellite regions of chromosomes within the same suprachromosomal families may undergo exchanges between nonhomologous chromosomes, thus increasing the mode and tempo at which these sequences evolve. However, the intrachromosomal recombination within alpha satellites appears to be the predominant evolutionary driving force. In general, the average intrafamily identity of alpha satellite monomers (~90%) is much higher than the interchromosomal identity (~75%). In addition, the average intrafamily identity within a species (99% in human and gorilla) is generally greater than that between species (90% between the human and gorilla satellite monomers). Humans and gorillas share the basic monomer as well as a higher-order repeat unit for suprachromosomal family 3, suggesting that this alpha satellite structure predates the human/great ape divergence. Thus, the alpha satellites within each species have evolved

in a ''concerted'' manner, giving rise to a significantly lower nucleotide divergence within a species than between species.

Alpha satellites have been found only within primate genomes, usually located around the centromere, and can bind key centromere proteins. Occasionally, however, ectopic centromeres are formed in noncentromeric segments of chromosomes, producing cytogenetic aberrations including visible karyotype disorders. These new centromeres were termed *neocentromeres*. However, not all neocentromeres detected in humans are derived from alpha satellites. About 60 reported neocentromeres completely lack alpha satellites but maintain their ability to bind main centromeric proteins. These neocentromeric sequences are promising material for the construction of artificial chromosomes. However, these results also suggest that centromeric repeats, including alpha satellites, may not have any essential role in the genome.

Table 1 lists other reported human centromeric satellites. The human *beta* (Sau3A) satellite family is defined by the 68-bp GC-rich monomer. This satellite is present in pericentromeric regions and in the short arms of human acrocentric chromosomes. *Gamma* satellite DNA was initially detected as a 220-bp repeat located on chromosome 8. A second subfamily of gamma satellite, *gamma X*, was identified in the centromeric region of the X chromosome. Both families share 220-bp units 62% identical to each other. The CER satellite family, characterized by the 48-bp unit, is present on chromosomes 13, 14, 15, 21, and Y.

Among poorly defined satellite families are the Sau (*Lsau*) and Sn5 families characterized by the 498- and 455-bp units, respectively. Many centromeric satellites listed in Table 1 were defined by sequence analyses. Classification of centromeric satellites continues, and additional families may be detected during the course of sequencing centromeric and heterochromatin regions.

2.2.2 Telomeric and Subtelomeric Repeats

In contrast to the highly variable monomers in centromeric satellites, the *TTAGGG* telomeric monomers are conserved in all vertebrates. They form tandem arrays 3 to 20 kb long and their conservation is indicative of the importance of telomeres for normal chromosomal maintenance and viability. Historically, telomeres have been found to be associated with the nuclear envelope, and they have been implicated in chromosomal positioning within the cell. Telomeres are implicated in aging, immortalization of cells, and chromosomal rearrangements.

The maintenance of telomeric repeats presents a unique challenge to the cell, since standard DNA replication would result in the progressive shortening of the telomere over time. The replication of human chromosomes is catalyzed by DNA polymerases. However, DNA polymerases require short template primers for the initiation of replication. Thus, the ends of chromosomes or telomeres would become gradually shorter over time through the exclusive use of this mode of replication. The length of telomeres is maintained by a special replication mechanism for the ends of chromosomes involving a telomere-specific terminal transferase. This enzyme, called *telomerase*, is a ribonucleoprotein (RNP), and it uses the RNA component as a template to initiate the replication of the telomeres. The enzymatic addition of bases is catalyzed by the protein component. Faithful replication of telomeres

protects chromosome ends from degradation, fusion, and recombination.

The length of telomeres appears to depend on the number of cell divisions with a general tendency toward shortening. This has been implicated in chromosomal aberrations, involving translocations in differentiated and abnormal cells. The length of telomeres has been used as a measure of the age of individual cells and is implicated indirectly in aging. It is still unclear whether changes in the telomere length have a direct impact on the aging process of a cell or whether they are the consequence of aging, possibly through a decrease in the telomerase fidelity.

The 100 to 300-kb long sequences adjacent to telomeric repeats are called *subtelomeric repeats*. They represent the boundary between the telomere and the rest of the chromosome. Most subtelomeric repeats contain motifs similar to TTAGGG, but there are exceptions such as *REP522*. Unlike telomeric repeats, most subtelomeric repeats are not substantially conserved in vertebrates. In fact, they are highly polymorphic in humans and even in different chromosomes. The distal ends of human chromosomes are characterized by an enhanced rate of recombination and aberrations in subtelomeric regions have been shown to be associated with several congenital abnormalities. The high divergence of subtelomeric repeats may prevent recombinations between nonhomologous chromosomes and increase their stability.

3 Interspersed Repeats

Usually, interspersed repeats are scattered remnants of transposable elements that were transpositionally active either in the human genome or genomes of our evolutionary ancestors. Active TEs have produced families and subfamilies of interspersed repeats of different age and size. There are over 600 families of human interspersed repeats represented in Repbase (Sect. 6.1). Most of them originated and became extinct during the last 30 to 150 million years but some of the oldest ones ceased to proliferate as long as 200 million years ago and are barely identifiable by sequence analysis. Detectable interspersed repeats represent ~45% of the human genome. Given the limits of detectability, it is very likely that the bulk of the remaining nonprotein coding DNA is also composed of very old, unrecognizable remnants of TEs.

The consensus sequence of a TE can be reconstructed by applying the so-called *simple majority rule* to its multiply aligned interspersed copies (Fig. 2). The average similarity of diverged repeats to their consensus sequence (y) is higher than the average similarity between individual repeats (x). The approximate relation between the two variables is given by the following simple formula:

$$y = \frac{1 + \sqrt{12x - 3}}{4}.$$

In many cases, consensus sequence is a quite accurate approximation of the original TE that generated a particular family of repeats. It can be further improved by correcting stop codons in open reading frames (ORFs) or restoring rapidly mutating CpG dinucleotides, which sometimes erroneously converge to CpA or TpG in the consensus sequence. At least one TE reconstructed this way, named *Sleeping Beauty*, has been shown to transpose *in vivo*.

Transposable elements harbored by the human genome can be divided into three

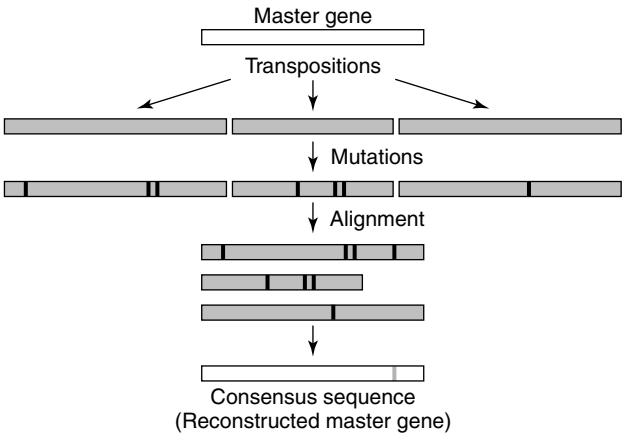

Fig. 2 Molecular paleontology of transposable elements. The top white rectangle represents an ancient active transposon that multiplied into interspersed repeats shown as gray rectangles subsequently marked by black vertical bars indicating mutations. Most of these mutations can be ''undone'' after multiple alignments and construction of a consensus sequence representing the reconstructed transposon (bottom white rectangle). The gray bar in the consensus sequence indicates an unresolved mutation.

groups. Two of these groups belong to a class of retroelements that include non-LTR retrotransposons and endogenous retrovirus-like elements also known as *long terminal repeat* (LTR) retrotransposons. Retroelements proliferate via reverse transcription of their RNA expressed in the host cell. An RNA copy of the transcribed retroelement is used as a template to produce its DNA copy, the so-called cDNA, which can be inserted in the genome. In non-LTR retrotransposons, a nick in the host DNA primes cDNA formation, whereas in retroviral-like elements, the DNA nicking and cDNA integration occur after reverse transcription. The nicking and cDNA formation are catalyzed by the endonuclease/integrase (IN) and reverse transcriptase (RT), respectively, encoded by the transposable element itself or by one of its autonomous relatives present in the genome. Unlike DNA transposons, active retroelements do not relocate from their original position.

The third group of TEs is represented by the *cut-and-paste* DNA transposons, called so because they are excised (cut) from the original genomic location and inserted (pasted) into a new site. Typically, a single enzyme called *transposase* mediates the process.

All groups of TEs are composed of autonomous and nonautonomous elements. An autonomous element encodes a complete set of enzymes characteristic of its family. Nonautonomous families use the protein machinery of their autonomous relatives. Therefore, the nonautonomous TEs can be viewed as parasites competing for enzymes encoded by the autonomous elements. Both groups also require additional cellular factors for amplification.

3.1 Non-LTR Retrotransposons

Detectable copies of non-LTR retrotransposons contribute ~34% of the human genome compared to the ~11% representing other detectable interspersed repeats. Non-LTR retroelements appear to be strictly intracellular parasites, inherited for millions of years rather than passed horizontally. For historical reasons, some autonomous non-LTR retrotransposons are referred to as long interspersed repeats (LINEs) due to the fact that they are several kilobases long. Analogously, their short nonautonomous associates are referred to as short interspersed repeats (SINEs). Autonomous non-LTR retrotransposons in eukaryotic species are currently divided into 13 superfamilies or clades: L1, CRE, NeSL, R4, R2, RTE, Tad1, R1, LOA, I, Ingi, Jockey, CR1, and Penelope. Only two of them, L1 and CR1 superfamilies are represented in the human genome. The human population continues to carry active elements of L1 non-LTR retrotransposons whereas CR1-like retroelements are extinct. L1-dependent Alu and SINE, VNTRs and ALU (SVA) nonautonomous retroelements also continue to proliferate in the human population.

3.1.1 L1 Non-LTR Retrotransposons

The typical L1 (or LINE1) autonomous retrotransposon is ~6 kb long, and contains two open reading frames referred to as ORF1 and ORF2, encoding the ~500-aa and ~1000-aa proteins, respectively (Fig. 3). The function of the L1-ORF1p protein is not well understood. Since it has a common leucine zipper (LZ) motif present in its sequence, it presumably binds RNA/DNA molecules. The L1-ORF2 protein includes the apurinic–apyrimidinic endonuclease (APE), reverse transcriptase (RT), and conserved cysteine-rich (C) domains. The endonuclease domain is involved in nicking the host DNA, followed by priming of an RNA-directed DNA synthesis that is catalyzed by the RT domain.

Out of several hundred thousand L1 copies present in the human genome, about 5000 are full-length elements and only around 100 contain intact open reading frames. In addition to ORF1 and ORF2, the full-length L1 elements contain 5′ and 3′ untranslated regions (UTRs), each several hundred bp long. The 5′ UTR includes a poorly characterized internal pol II transcription promoter. Unlike most human genes that contain pol II promoters upstream of the transcription start site, the L1 promoter is located downstream of the start site. Occasionally, the 5′ L1 UTR may also promote transcription that starts in the strand complementary to the 5′ UTR and extends to the genomic region flanking the L1 5′ end. The 3′ L1 UTR includes an AATAAA polyadenylation signal and a polyA tail.

In addition to the transcription, the L1 life cycle includes export of the transcribed

Fig. 3 Schematic structure of the L1 non-LTR retrotransposon. It consists of a 5′ untranslated region (5′ UTR) with pol II internal promoter, two open reading frames (ORF1 and ORF2), a 3′ untranslated region, a polyA signal (AATAAA), and a polyA tail. L1 elements are flanked by target site duplications (TSDs). The ORF1 protein includes a conserved leucine zipper motif (LZ). The ORF2 protein includes domains for the apurinic/apyrimidinic-like endonuclease (APE), RT, and a conserved cysteine-rich motif (C).

RNA from the nucleus to the cytoplasm, translation and formation of ribonucleoprotein particles, which are transported back into the nucleus, reverse transcription, and integration into the genome. L1 elements lack splice signals and therefore, L1 mRNA is bi-cistronic with two open reading frames separated by a short noncoding spacer. Translation of ORF1 is likely to be initiated at the 5′ UTR by ribosomal scanning. ORF2 translation may be initiated by an internal ribosomal entry site (IRES) or by the so-called *ribosomal shunting* or *jumping*. Also, it is unclear how the L1-encoded proteins enter the nucleus. Usually, nuclear export of proteins as large as those encoded by ORF1 and ORF2 is driven by specific amino acid sequences called *nuclear localization signals*. As there are no known nuclear localization signals encoded by either ORF1 or ORF2 proteins, the mechanism involved in their entry into the nucleus remains a mystery. It is even unclear if the ORF1 translation products ever enter the nuclear compartment.

The model of reverse transcription and integration of L1 into the genome invokes a coupled process known as *target-primed reverse transcription* (TPRT). According to this model, the APE domain of the ORF2 protein recognizes a 6-bp target site described by the TTAAAA consensus sequence, and nicks the second DNA strand between the bases complementary to TT and AAAA (Fig. 4). The free 3′-OH end of the nick is then used for priming reverse transcription of L1 RNA by the ORF2 reverse transcriptase, starting from the 3′ polyA tail. Eventually, a second nick is created on the first strand, preferably ~15 bp downstream of the first nicking site, leading to a staggered break and, after integration, to the formation of target site duplications (TSDs) flanking the integrated sequence. The typical size of TSDs generated by L1 retrotransposition is ~15 bp, but the size may vary and sometimes even short deletions of target sequences are observed. The final integration steps, including

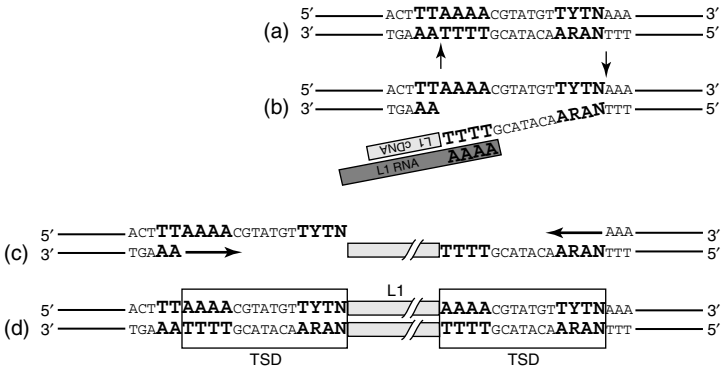

Fig. 4 The target-primed reverse transcription (TPRT) mechanism. (a) The L1 endonuclease cleaves the antiparallel DNA strand between 3′ AA and 3′ TTTT, and exposes a free 3′ hydroxyl group at the nick, serving as a primer for reverse transcription of L1 mRNA. (b) The second nicking occurs ~15 nucleotides from the first nicking site, preceded by a TYTN consensus sequence. (c) The remaining steps include elimination of L1 RNA, DNA synthesis, and repair, probably mediated by the host enzymes. (d) Integrated L1 retroelement and its flanking sites.

synthesis of the second strand, ligation, and elimination of the L1 RNA, are probably mediated by host enzymes.

The majority of L1 elements undergo 5′ truncations and inversions during retroposition and, as a result, they are represented mostly by 3′ terminal portions that are shorter than 1 kb in length. Possible reasons for the truncation may be digestion of the L1 RNA by cellular ribonucleases, or premature termination of the reverse transcription, or both.

Occasionally, transcription of L1 elements does not stop at the L1 polyadenylation signal but continues until another transcription termination signal encoded by the host DNA is encountered. As a result, host sequences adjacent to the 3′ L1 terminus and the new polyA sites may be transduced by the L1 to a new genomic location. Over 10% of the analyzed L1 insertions in the human genome contain 3′ transduced sequences that range from 30 bp to several kb in length. This represents an attractive mechanism that could be involved in exon shuffling in the host genome. However, no real exons have yet been detected in L1-transduced sequences. Therefore, it is possible that the L1-mediated 3′ transduction is suppressed in the vicinity of human genes. Some L1 retrotransposons can also be accidentally transcribed from upstream promoters leading to transduction of genomic DNA flanking the 5′ ends of L1 elements. Also, new L1 subfamilies can be generated by the addition of both 5′ and 3′ flanking DNA.

3.1.2 L1-dependent Nonautonomous Non-LTR Retrotransposons

There are two major groups of L1-dependent non-LTR retrotransposons present in the human genome: processed pseudogenes, and SINEs that include Alu and SVA elements. Elements from both groups are flanked by ~15-bp TSDs, have the 3′ polyA tails, and are inserted preferentially into the TTAAAA target sites. It has also been demonstrated experimentally that the propagation of processed pseudogenes and Alu elements is mediated by the L1-encoded RT. Therefore, both processed pseudogenes and Alu repeats are classified as nonautonomous non-LTR retroelements mobilized by the L1 retroposition machinery. The L1 reverse transcriptase, in a cis-acting manner, preferentially binds the same mRNA molecule it was translated from. Therefore, Alu and other nonautonomous retropseudogenes probably intercept the L1 RT while interacting with ribosomal components.

3.1.2.1 **Processed pseudogenes** Processed pseudogenes, or retropseudogenes, are products of occasional retrotransposition of spliced mRNA formed during regular transcription of the host genes (Fig. 5). Since transcription of these genes is usually driven by external pol II promoters, processed pseudogenes do not include the promoters. Therefore, it is extremely unlikely that they can be repeatedly transcribed and retrotransposed. Nevertheless, the human genome is estimated to contain at least 30 000 retropseudogenes formed from a variety of host genes. The most abundant retropseudogenes appear to be derived from highly expressed genes ranging from those coding for small nuclear, nucleolar, and cytoplasmic RNA, to those coding for ribosomal proteins.

3.1.2.2 **Alu repeats** Alu elements were first discovered using DNA renaturation–reassociation experiments that were performed during the early era of repeat studies. They are represented by more

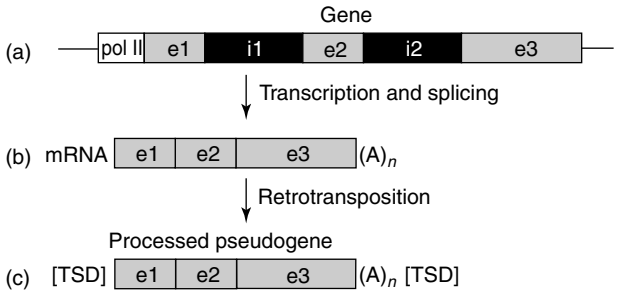

Fig. 5 Formation of processed pseudogenes (retropseudogenes). (a) The original gene that is transcribed into RNA, excluding pol II promoter. Exons e1–e3 and introns i1, i2 are indicated. (b) mRNA afer splicing and polyadenylation. (c) L1-retrotransposed, processed retropseudogene with ~15 bp TSDs.

than one million copies in the human genome, which makes them numerically the most abundant of all human interspersed repeats. The name ''Alu'' is derived from an *AluI* restriction site present in these elements.

Full-length Alu elements are ~300-bp long (Fig. 6) dimers composed of two homologous 120- and 148-bp left and right monomers respectively, derived from the *7SL RNA* gene ~100 million years (Myr) ago. The 7SL RNA molecule is an important component of the signal recognition particle (SRP) that binds to nascent signal sequences and transiently arrests translation. The *7SL RNA* gene contains the pol III internal promoter composed of the conserved ~15-bp A and B boxes. The right monomer contains an additional 31-bp 7SL-derived sequence

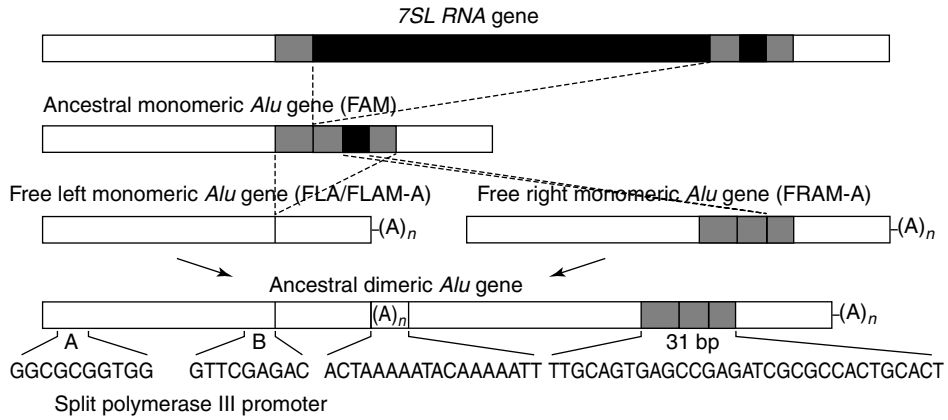

Fig. 6 A scheme for the origin and early evolution of human Alu master (source) genes. Dimeric Alu was derived from the *7SL RNA* gene after a two-step deletion process leading first to an ancestral family of Alu-like monomers (FAM) and then to other monomers, of which two, FLA/FLAM-A, and FRAM, merged into a precursor of dimeric Alu characteristic of primates.

relative to the left monomer, and the monomers are separated by the A-rich central region. The right monomer also contains a 3′-oligo-dA-rich tail (or polyA tail), usually 20 to 30 bp long. Free Alu monomers such as FLA, FLAM, and FRAM were very active during the early era of Alu evolution, and at least one of them, BC200, has been recruited as a regulated gene expressed in the brains of higher primates.

Probably around one hundred Alu elements out of one million appear to be currently participating in retrotransposition. It is unclear why Alu retroposition is confined to this limited number of ''master'' or ''source'' genes. One often invoked explanation is that most retroposed elements remain untranscribed. For example, pol III transcription depends on flanking sequences and most Alu elements may be inserted into genomic sites that do not complement their pol III promoters. Furthermore, most Alu sequences are heavily methylated at CpG positions that are also present in the promoter region. The methylation occurs at position 5 of cytosine residues. Deamination of 5-methyl cytosine produces thymine – a mutation that is likely to escape the repair mechanism. As a result, CpG dinucleotides mutate to TpG and CpA at a rate approximately ten times higher than that of the non-CpG dinucleotides. Other regions of rapid mutations include A-rich linker and tail regions often associated with microsatellite expansion. This rapid rate of mutations represents another potential way to eliminate or mitigate the ability of any particular Alu repeat to mobilize. Thus, the majority of Alu repeats appear to be fossil relics that integrate in the genome and accumulate mutations in a random manner, characteristic of pseudogenes.

The human Alu family has been divided into nine major subfamilies: AluJo, Jb, Sz, Sx, Sg, Sq, Sp, Sc, and Y, ordered approximately from the oldest to the youngest (Table 2). AluJo and Jb form a separate branch distinct from the AluS branch that includes all the other seven major subfamilies. Each Alu subfamily represents a set of elements derived from a small group of closely related master genes. As a result, members of the same family share, in principle, the same consensus sequence, which is different from

Tab. 2 Average chromosomal density and estimated age of major Alu subfamilies.

Alu subfamily[a]	*AluJo*	*AluJb*	*AluSz*	*AluSx*	*AluSg*	*AluSq*	*AluSp*	*AluSc*	*AluY*

[d] Age (in million years), based on Kimura's distance.

consensus sequences for other subfamilies. AluJo and AluJb are the two oldest subfamilies that proliferated ~65 million years ago. AluY is the youngest among major AluS subfamilies as it was retrotransposed 5–30 million years ago. AluY gave rise to a number of still younger sub(sub)families of which the following 22 have been reported so far: AluYa1, Ya4, Ya5, Ya8, Yb3a1, Yb3a2, Yb8, Yb9, Ybc3a, Yc1, Yc2, Yd2, Yd3, Yd3a1, Yd8, Ye2, Ye5, Yf1, Yf2, Yg6, Yh9, Yi6. At least some of these sub(sub)families still contain elements actively proliferating in human populations, as indicated by their insertion polymorphism. Among the largest and best-studied active sub(sub)families are AluYa5 and Yb8. However, some of the smaller ones such as AluYb9, Yc2, Yg6 and Yi6 are also of growing interest in human population genetics studies.

Densities of recently retroposed Alu elements are about three times higher on chromosome Y than on chromosome X, and about two times higher than on autosomes. This indicates that Alu elements are primarily retroposed in paternal germlines. However, these original chromosomal proportions change very rapidly with time. The most striking long-term trend is the accumulation of Alu elements in GC-rich and gene-rich regions. At the same time L1 elements are predominant in AT-rich and gene-poor regions. Given that newly retrotransposed Alu and L1 elements are inserted into regions of similar GC content, the evolution of the human genome is characterized by massive subsequent redistributions of Alu repeats. The most likely factor involved in the redistributions may be related to the different patterns of postinsertion duplications and deletions.

3.1.3 CR1-like Non-LTR Retrotransposons

CR1 is one of the most abundant and widely distributed clades of non-LTR retrotransposons that are present in the genomes of birds, amphibians, fishes, reptiles, invertebrates, and mammals. Typically, autonomous CR1-like elements are several kb long and contain two open reading frames, ORF1 and ORF2, coding for multidomain proteins. The ORF1p may be involved in DNA/RNA binding, but other interesting functions are also likely (see below). The ORF2 protein includes the APE and RT domains, which are distantly similar to those identified in the L1 ORF2 protein. CR1-like elements do not generate target site duplications.

3.1.3.1 L2 and L3 retroelements

Two human families of long interspersed repeats called L2 and L3 were most likely amplified from active autonomous CR1-like retroelements (Fig. 7). Given the high sequence diversity, their retrotransposition probably occurred 200 to 300 million years ago, long before mammalian radiation. Together with the nonautonomous elements described below, L2 and L3 represent ~5% of the human genome. Most of the preserved L2 and L3 copies are 5′ truncated, which, in addition to their very old age, impedes reconstruction of their source genes. For example, the ~3300-bp L2 consensus sequence does not seem to contain the ORF1 protein that is present in other CR1-like retroelements. However, it is not clear whether this is due to incomplete reconstruction or because the active L2 source gene lacked such a protein. The ORF1 protein is present in the L3 consensus sequence, and it contains the esterase domain that is also present in the ORF1 proteins encoded by CR1-like elements in birds, reptiles, and fishes. Unlike L1, neither L2 nor L3 elements are flanked

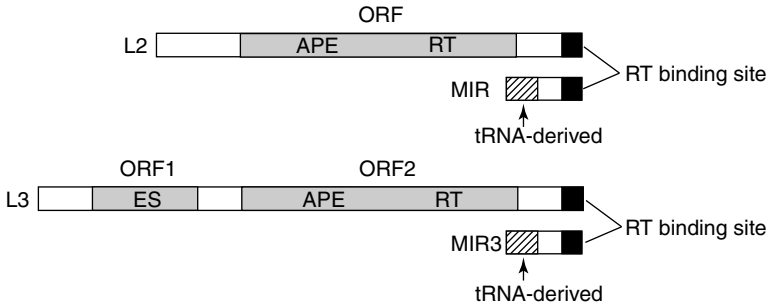

Fig. 7 L2 and L3 autonomous CR1-like retrotransposons and their nonautonomous companions MIR and MIR3. L2 and L3 encode enzymes containing endonuclease (APE) and reverse transcriptase (RT) domains. L3-ORF1 is homologous to esterase (ES).

by target site duplications. Furthermore, instead of the 3′ polyA tail, L2 and L3 carry the $(TGAA)_3$ and $(GATTCTAT)_2$ microsatellites at their 3′ termini respectively.

3.1.3.2 **Nonautonomous MIR and MIR3 elements** MIR and MIR3 are considered to be nonautonomous elements amplified by L2- and L3-encoded proteins, respectively. MIR is a classical 262-bp SINE element derived from a tRNA-like sequence and a 50 bp sequence fragment homologous to the 3′ terminus of the L2 element (Fig. 7). This terminus was probably recognized by the L2-encoded RT that led to amplification of MIRs. Approximately 4% of the human genome is made up of L2 and MIR copies.

MIR3 is viewed as a nonautonomous element that parasitized the L3 retroposition machinery (Fig. 7). Analogously to MIR and L2, MIR3 and L3 also share the ~50-bp 3′ termini, which are likely to serve as binding sites of the L3-encoded RT. In addition, the ~140-bp 5′ terminal portions of the MIR3 and MIR consensus sequences are 81% identical to each other. This portion is homologous to tRNA and probably includes the pol III internal promoter essential for proliferation of MIR3 and MIR retroelements. Approximately 0.5% of the human genome is derived from L3 and MIR3 elements.

3.2 LTR Retrotransposons

Human long terminal repeat retrotransposons are retrovirus-like elements retrotransposed in the genome and inherited by the host from generation to generation. It is believed that human LTR retrotransposons are descendants of exogenous retroviruses that repeatedly infected germlines of human ancestors and became endogenous. Endogenous retroviruses retain their ability to retrotranspose within cells for some time, but cannot be transmitted efficiently between cells. Their subsequent evolution reflects adaptation to an intracellular environment, simplification, and formation of nonautonomous copies.

Most human endogenous retroviruses (HERVs) are extinct and are represented only by mutated interspersed copies, particularly by LTRs. The interspersed copies of LTR retrotransposons constitute around 9% of the human genome. Although LTR retrotransposons are not as abundant as

the non-LTR retrotransposons, they are by far the most diverse and complex TEs harbored by our genome. Approximately 200 families of LTR retrotransposons have been identified in the human genome. A vast majority of them were identified and reconstructed using computer-assisted sequence analysis.

On the basis of the similarities to known animal exogenous retroviruses, all LTR retrotransposons present in the human genome can be divided into three classes (Table 3).

Class I non-LTR retrotransposons are similar to gamma retroviruses including mammalian type C retroviruses such as murine leukemia virus (MLV). All elements from this class are flanked by 4- and 5-bp TSDs that are generated upon their integration in the genome (Table 4).

Class II non-LTR retroelements are similar to beta retroviruses represented by mammalian type B and D retroviruses such as the mouse mammary tumor virus (MMTV), Mason-Pfizer monkey virus, and primate lentiviruses. The latter include human immunodeficiency virus (HIV). All Class II retroelements are characterized by 6-bp target site duplications (Table 5). They were probably active in hominoids including *Homo sapiens*.

Class III families represent the oldest LTR retrotransposons detected in the human genome. Some of them were active in the common ancestor of primates and other mammals. Class III elements amplified to a larger copy number than Class I and Class II elements together. Class III families are related to spumaviruses such as human foamy virus, and they are characterized by 5-bp target site duplications (Table 6).

Structural features of LTR retrotransposons

A typical retrovirus is inserted into the genome in the form of a provirus containing two copies of 200 to 3000-bp long LTRs, which are identical to each other at the time of insertion (Fig. 8). Most LTRs have conserved 5′-TG and CA-3′ termini, but in some families such as HERVK11 and HERVK11D, LTRs contain TA-3′ termini instead of CA-3′. The internal portion of a provirus is defined as a sequence flanked by LTRs. Usually

[a]This family is also known as HERV-S.

it is several kb long, and encodes a set of proteins necessary for the retroviral life cycle. These proteins are encoded by the *gag* (group specific antigen), *pro* (protease), *pol* (polymerase), and *env* (envelope) genes (Fig. 8). Also, some Class II and Class III retroviruses encode deoxyuridine triphosphatase (dUTPase).

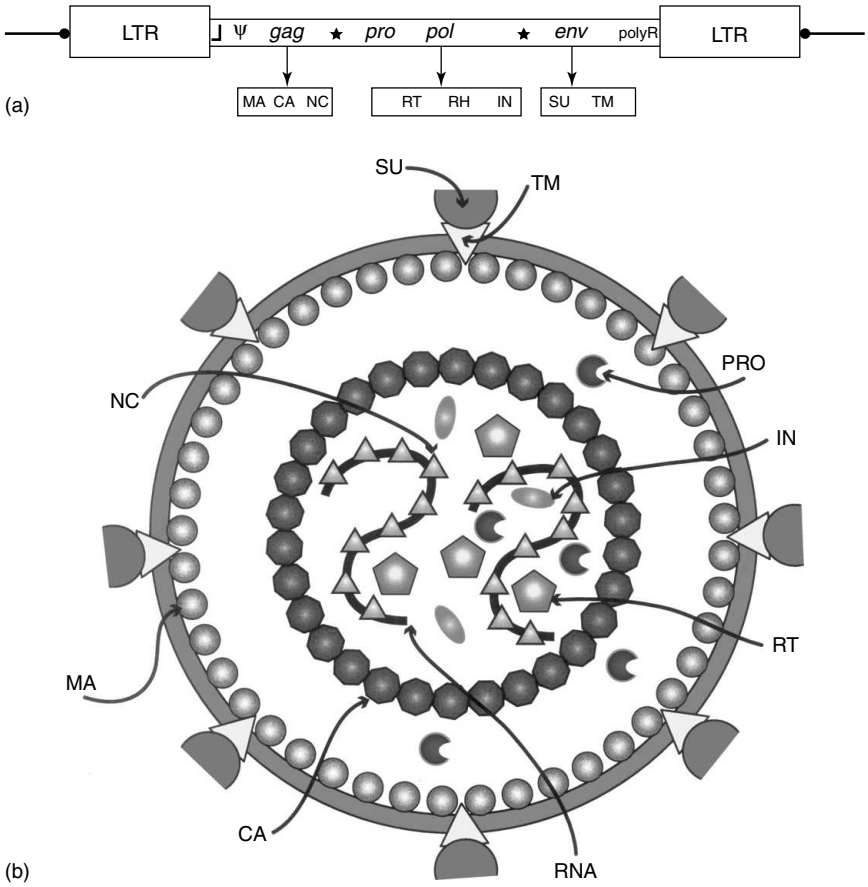

Fig. 8 The general structure of LTR retrotransposons. (a) Structural features of a provirus. Black circles indicate target site duplications; LTR, long terminal repeat; ⌟, primer binding site; Ψ, packaging signal; *gag*, capsid protein gene; *pro*, protease gene; *pol*, polymerase gene; *env*, envelope protein gene; ★, deoxyuridine triphosphatase (dUTPase), which lies between *gag* and *pro* in some Class III retroviruses, and between *pol* and *env* in Class II retroviruses. PPT stands for polypurine tract. The *pro* gene encodes the protease (PR), involved in the processing of the *gag*-, *pol*-, and *env*-encoded proteins. The *pol* gene encodes the reverse transcriptase (RT), ribonuclease H (RH), and integrase (IN). The *env* gene encodes the surface (SU) and transmembrane (TM) proteins. Typically, the *gag* gene encodes the matrix (MA), capsid (CA), and nuclear capsid (NC) structural proteins. (b) Schematic structure of a retroviral particle. The viral envelope (green) is made of a host-cell-produced lipid bilayer. It harbors multiple complexes formed by the *env*-encoded TM and SU components linked together by disulfide bonds. The retroviral capsid formed by the CA surrounds two RNA copies of the retrovirus, tRNAs, RT, IN, and PR. (See color plate p. xxiii).

Historically, LTR retrotransposons were viewed as endogenous retrovirus-like elements that did not encode the env protein. Currently, they are considered as nonautonomous retrovirus-derived elements, and the originally introduced distinction between retroviruses and LTR retrotransposons is becoming obsolete.

Gag is a multifunctional structural polyprotein separated into matrix, capsid, and nucleocapsid structural proteins by the *pro*-encoded protease (PR), which is related to cellular aspartic proteases.

The *pol* gene encodes a polyprotein precursor processed by the protease to reverse transcriptase and integrase. RT contains a ribonuclease H domain (RH), which digests RNA strands in RNA–DNA duplexes. RT encoded by LTR retrotransposons is capable of both RNA- and DNA-dependent DNA syntheses. It is the most conserved endoretroviral protein. The retroviral IN may be distantly related to $DD_{35}E$ transposases (see Sect. 3.3.2).

The *env*-encoded protein precursor is cleaved by the protease into the envelope, surface and transmembrane glycoproteins. It is thought that viral particles bind host cells through interactions between the surface glycoproteins and specific cell surface receptors (Fig. 8). Such interactions trigger fusion of the cell and virus membranes, followed by intrusion of the virus into the cell cytoplasm.

Transcription Transcription of the provirus starts at the pol II promoter present in the long terminal repeat (see LTR; Fig. 8a; Fig. 9). LTR is composed of three regions, called U3, R, and U5. The U3 region contains the pol II promoter. Additional signals affecting transcription, including enhancers, were also detected in the U3 region. The start of the LTR transcription corresponds to the U3-R boundary. Conversely, the R-U5 boundary is defined by the transcription stop-site. The transcription termination is mediated by the AATAAA or ATTAAA polyadenylation signals usually present in the U3 region. Therefore, the transcription is terminated in the second LTR only. In some retroviruses, including HIV, the polyadenylation signal is placed downstream of the U3-R boundary. However, the first LTR is still bypassed during transcription, presumably due to suppression of the transcription termination by a small distance between the transcription start-site and the polyadenylation signal.

Reverse transcription Reverse transcription of retroviral RNAs occurs in the cytoplasm of the infected host cell. It begins either when the viral particles enter the cytoplasm or when nuclear transcription of the already integrated provirus produces its functional RNA. The cytoplasmic localization of the retroviral reverse transcription is in sharp contrast to nucleus-based reverse transcription of non-LTR retrotransposons (Fig. 4). The retroviral reverse transcription is believed to follow a multistep process outlined schematically in Fig. 9 and described below.

1. The reverse transcription starts with the minus-strand DNA synthesis primed by the 3′ end of a tRNA molecule annealed to the primer binding site (PBS). Usually, the PBS is complementary to the ~18-bp 3′ end of the virus-specific tRNA that starts just a few nucleotides downstream of the U5 region.
2. Minus-strand DNA synthesis proceeds to the 5′ end of the RNA, producing a 100 to 150 bp DNA molecule called *minus-strand strong-stop DNA*, which is released from the original RNA–DNA duplex by the RNaseH mediated digestion of the complementary RNA.
3. Following the digestion, the minus-strand strong-stop DNA performs the first strand transfer, annealing to the R-region at the 3′ end of the plus-strand RNA.
4. After the strand transfer, minus-strand DNA synthesis continues, and it is

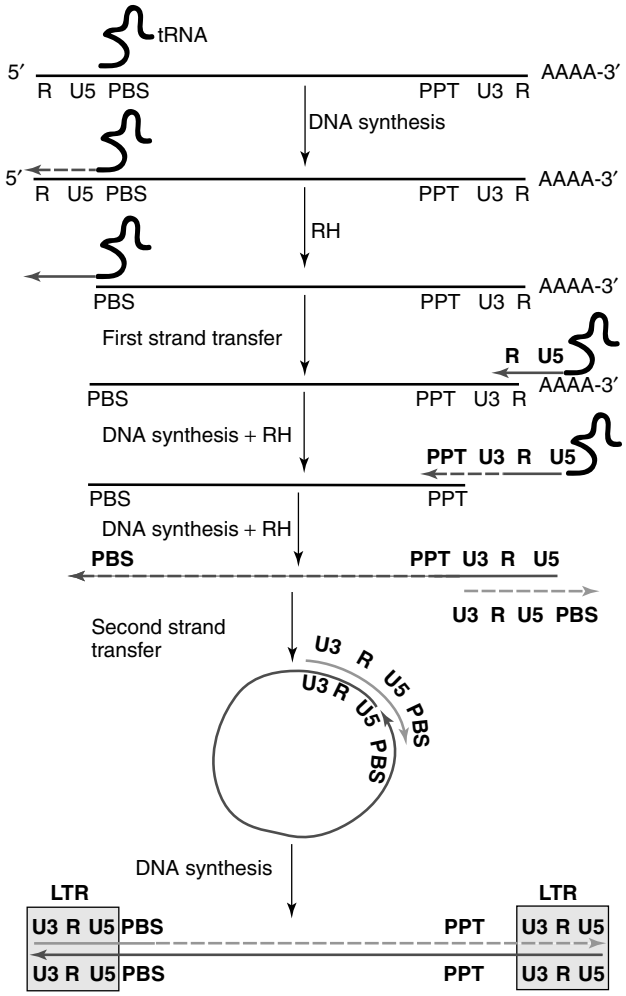

Fig. 9 Reverse transcription of the retroviral RNA. Dotted lines mark newly synthesized DNAs; green, plus-strand DNA; red, minus-strand DNA; RH, RNaseH digestion of RNAs. (See color plate p. xxiv).

accompanied by digestion of the RNA template, except for a short RNaseH-resistant polypurine tract (PPT).

5. The 3′ end of the PPT primes plus-strand DNA synthesis, which continues until the PBS-like portion of the tRNA molecule is reverse transcribed. As a result, the so-called *plus-strand strong-stop DNA* is generated.
6. RNaseH digests the PBS-annealed tRNA molecule.
7. The second strand transfer is performed by annealing the complementary PBS segments present at the termini of the plus-strand and minus-strand DNAs.
8. The plus and minus DNA strands serve as templates for each other.

The replication is completed when RT synthesizes the entire plus and minus DNA strands. The final product is a linear duplex DNA.

Life cycle of LTR retrotransposons The life cycle of an LTR retrotransposon starts with the transcription of its provirus copy integrated in the genome. The resulting mRNA is transported from the nucleus to the cytoplasm, where it is translated. Usually, reverse transcription of the proviral mRNA occurs in the viral particles in the cytoplasm. The resulting cDNA is then transported back to the nucleus, together with the retroviral integrase where the integrase inserts the cDNA into the host genome, producing a new provirus flanked by identical LTRs and short TSDs.

Subsequent homologous recombination between the LTRs may result in elimination of the provirus with the exception of a solo LTR (Fig. 10). The number of endogenous retroviruses that retain their internal portions flanked by both LTRs is about ten times smaller than the number of solo LTRs. Therefore, recombination between the flanking LTRs is a significant factor in elimination of LTR retrotransposons. Gene conversion between LTRs can also occur at a very low rate. Therefore, the average divergence between proviral LTRs does not adequately reflect the age of the corresponding family of LTR retrotransposons.

RNA recombination of LTR retrotransposons LTR retrotransposons copackage two copies of their RNAs, which can recombine with each other, in the same viral particle. Two RNAs representing essentially distinct LTR retrotransposons can also be copackaged together if they share similar ψ packaging signals. Retroviral recombination is usually mediated by the RNA template switch that occurs during minus-strand DNA synthesis, when RT is paused by a break in the reverse transcribed RNA. The RT pausing can also be caused by a specific secondary structure of the RNA template and by internal repeats.

Characteristics of human LTR retrotransposons The most abundant and ancient group of LTR retrotransposons preserved in the human genome are class III retrotransposons (Table 6). For example, the HERVL16 and HERVL33 families are more than 200 million years old. Despite their high abundance, they have remained undetected for a long time due to their extensive modification by mutations. Most

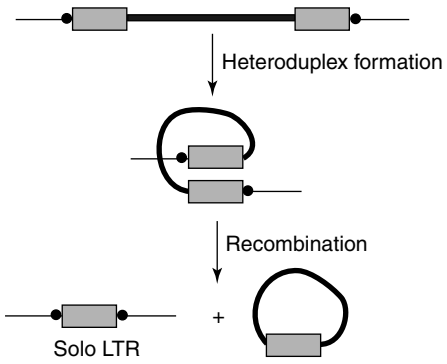

Fig. 10 Formation of a solo LTR through the illegitimate recombination between proviral LTRs.

Class III families of retroelements reconstructed so far are nonautonomous, including HERV-L, which was discovered as the first representative of class III elements. For example, the HERV-L family does not contain *env*, HERVL66 misses *gag* and protease, and HERVL68 does not encode any proteins at all. The most abundant Class III families are MaLRs (Mammalian apparent LTR retrotransposons) and THE1 elements, which probably did not encode any functional proteins at the time of their activity. MaLRs (THE1) were recently classified as members of Class III based on the observation that some of their noncoding sequences were derived from HERV-L-like elements. HERV18 was the first Class III element found to contain *env*. Many different families of LTR retrotransposons are still represented by their LTRs only. As shown in Tables 4 and 6, these families were reliably assigned to their proper classes based on similarities to LTRs from classified retroelements.

Class I LTR retrotransposons (Table 4) include dozens of nonautonomous families that are members of the same group, also called the MER4 or MER4I group after the MER4 element that was discovered over a decade ago and later identified as an LTR flanking the internal portion of a retrovirus-like element (MER4I). Other Class I families of LTR retrotransposons were discovered and classified on the basis of their sequence similarity to MER4I. All these families are characterized by 4-bp target site duplications. Analogously to MaLR and THE1 elements, the originally discovered MER4I-like retrotransposons, do not code for any proteins. Furthermore, the human genome also harbors autonomous Class I families whose members were ancestral to nonautonomous MER4I-like elements. For example, the internal portion of the PRIMA4 autonomous retrovirus is similar to the entire MER4I sequence; even their LTRs are similar. Analogously, the autonomous PRIMA41 retrovirus is an ancestor of the MER41 family of MER4I-like nonautonomous elements. Class I elements were involved in vigorous multiple recombinations between RNA copies of different retroviruses. As a result, many Class I families are chimeras composed of parts that came from retroviruses dissimilar to each other, for example, *Harlequin*.

Class III and Class I elements were probably engaged in extensive complementation, meaning that various families mutually assisted each other by sharing necessary enzymatic and packaging activities. For instance, the RNA of nonautonomous proviruses can be copackaged into functional viral cores produced by autonomous LTR retroelements and exogenous retroviruses. These viral cores can be released from the host cell and can infect other cells. Given the low fidelity of reverse transcription ($\sim 10^{-5}$ per nucleotide per cDNA molecule), the original nonautonomous retrovirus can be dramatically transformed after multiple rounds of reverse transcription and intercellular migrations. As a result of such transformation, the similarity between the original provirus and the transformed retrotransposon can wane rather fast.

Human Class II elements are represented by 11 families (Table 5) with ages ranging from ~35 million to less than 5 million years. The oldest Class II family is HERVK22. On the other hand, some HERVK10 elements are polymorphic in the human population, and contain nearly intact ORFs coding for the standard retroviral proteins. In addition to the standard proteins, some HERVK elements encode dUTPase and K-Rev. The latter is a 105-aa

protein, also called cORF, which is a functional homolog of the HIV Rev protein. K-Rev mediates nuclear export of the unspliced HERVK RNA by binding to both the host Crm1 nuclear export factor and to a cis-acting retroviral RNA target.

Mechanisms of retroviral evolution are poorly understood since very few intermediate forms of exogenous retroviruses are available for analysis. Therefore, LTR retroelements deposited in mammalian genomes provide us with a unique opportunity to study retrovirus-like elements, which became extinct millions of years ago.

3.3 DNA Transposons

All DNA transposons detected in the human genome represent the so-called *cut-and-paste* category since they use excision from host DNA (cut) followed by reinsertion (paste) as two basic steps in their life cycle. Both steps are mediated by the transposon-encoded enzyme called *transposase*, which recognizes terminal inverted repeats (TIRs; Fig. 11). The transposon insertion is accompanied by target site duplication.

The cut-and-paste process is thought to be associated with the active replication process. As shown in Fig. 12, the excision is more likely in already replicated DNA segments, whereas the insertion occurs preferentially in nonreplicated segments. On the basis of this model, the predicted multiplication rate of cut-and-paste DNA transposons is 1.5 per replication cycle; but the real rate is expected to vary between 1 and 1.5.

To date, no active DNA transposons have been found in the human genome. All

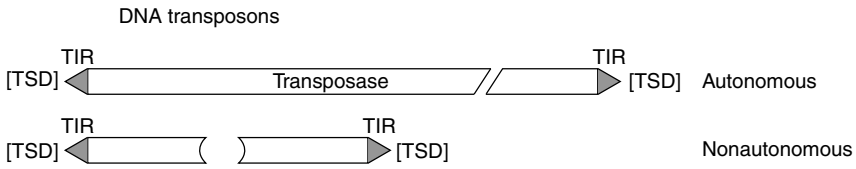

Fig. 11 Schematic structure of autonomous and nonautonomous DNA transposons.

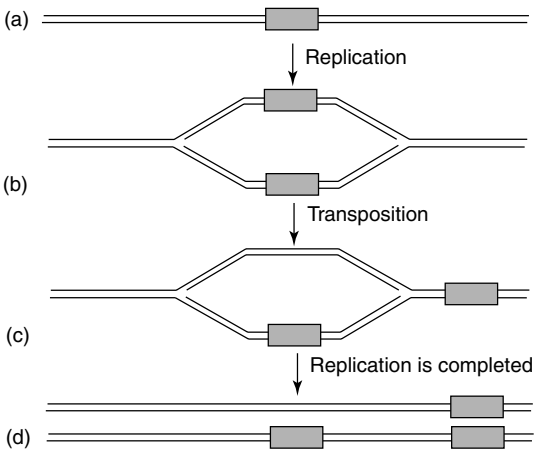

Fig. 12 Relationship between DNA transposition and host replication.

basic properties of human DNA transposons were deduced from sequence analysis of human repetitive DNA, followed by reconstruction of DNA and protein sequences encoded by once-active elements. On the basis of their structural commonalties, eukaryotic DNA transposons can be divided into eight different superfamilies, of which six are represented in the human genome (Table 7). DNA transposons that belong to the same superfamily, even those from different vertebrates, plants, and insects, are characterized by common structural hallmarks such as similar TIRs, transposases, and the same characteristic sizes of TSDs. Additional superfamily characteristics include conserved termini of TIRs, usually 2 to 3 bp long. Like other classes of TEs, DNA transposons are represented by autonomous and nonautonomous elements.

The human genome harbors families derived from over 29 autonomous transposons. Of these, over 25 belong to the hAT and *mariner/Tc1* superfamilies (Table 8). However, only 13 of them have been reconstructed and characterized in more detail. Some of the most abundant families of nonautonomous hAT elements, such as MER5A and Cheshire_A, are represented by more than 10^4 copies each. Overall, the transposon-derived interspersed repeats account for ~5% of the human genomic DNA.

3.3.1 hAT-like Transposons

The superfamily of hAT-like elements was named after the initials of *hobo, Activator* and *Tam* transposons identified in the fruit fly and maize. They are flanked by ~15-bp terminal inverted repeats that include characteristic 5′-CA and TG-3′ termini, and generate 8-bp target site duplications upon integration in the genome. Autonomous hAT-like transposons are ~3000-bp long and encode ~500-aa transposase similar to transposases encoded by all known hAT-like transposons detected in different eukaryotic species. Analogously, the ORFs in the human hAT-like transposons are also expected to encode the transposases.

The most abundant hAT elements are the nonautonomous deletion products of the corresponding autonomous transposons. They retain TIRs, but the

transposase is either partially or completely deleted. Typically, the number of nonautonomous copies representing a particular hAT family is at least an order of magnitude higher than the copy number of the corresponding autonomous elements. Sometimes, nonautonomous elements differ from their autonomous companions by possessing additional internal fragments (for example, MER5A-B and *Charlie10*). It is possible that these additional fragments represent genomic DNA

captured by the nonautonomous transposons (analogously to MuDR transposons in the *Arabidopsis thaliana* genome).

The most abundant human hAT families are *Charlie10, Charlie5, Cheshire* and their nonautonomous companions represented by ~60 000, ~50 000 and ~40 000 copies respectively (see Table 8). As indicated above, there are no active DNA transposons in the human genome. The youngest hAT elements are *Charlie3* repeats that are ~8% diverged from their family consensus sequence. Given the standard neutral mutation rate in the human genome, this corresponds to ~35 million years. Most of the human hAT-like families are much older and they might have been active in a common ancestor of primates and rodents.

3.3.2 Mariner/Tc1-like Transposons

The Mariner/Tc1 superfamily reflects the names of the two founding DNA transposons *mariner* and *Tc1,* first discovered in the *Drosophila melanogaster* and *Caenorhabditis elegans* genomes. Members of this superfamily are characterized by 2-bp target site duplications (usually TA), by ~28-bp TIRs, and by the 5′-CA...TG-3′ termini. However, some elements may have different termini; for example, HSMAR1 and HSMAR2 are characterized by the 5′-TT...AA-3′ and 5′-CG...CG-3′, respectively. Mariner/Tc1 transposases are distantly related to a broad set of bacterial transposases similar to that encoded by IS630 insertion element, and are characterized by the conserved $DD_{35}E$ motif.

3.3.3 piggyBac-like Transposons

The piggyBac superfamily includes DNA transposons with TTAA TSDs, the ~15-bp terminal inverted repeats, the 5′-CCC and GGG-3′ termini, and the unique piggyBac transposase. The piggyBac transposon was first discovered as an active mobile element in the cabbage looper, *Trichoplusia ni*. The human transposon called *Looper* was the first piggyBac-like element identified outside cabbage looper. It was reconstructed from copies transposed ~100 million years ago. Since then, piggyBac-like elements were identified in nonmammalian vertebrates, insects, and fishes. In addition to Looper, the human genome harbors MER75 and MER85 transposons that were active 10 to 50 million years ago. Only ~2000 copies of the piggyBac-like elements are present in the human genome.

3.3.4 MuDR-like Transposons

MuDR/Mu transposons, also known as *Mutators*, were first discovered in maize. They are characterized by 9 to 10-bp TSDs and by ~70 to 400-bp TIRs, typically ending with 5′-GGG and CCC-3′ conserved termini. However, some families of MuDR transposons in the *A. thaliana* genome can transpose without any discernible TIRs. Different autonomous MuDR transposons encode similar MuDR-like transposases, which share common conserved motifs with bacterial IS256-like transposases. Currently, only two families of MuDR-like transposons are known to be harbored by the human genome. One of them is represented by the nonautonomous transposons Ricksha and Ricksha_0, and characterized by 9 to 10-bp TSDs, ~70-bp TIRs, and 5′-GGG and CCC-3′ termini. Ricksha and Ricksha_0 were active 40 to 100 million years ago and are present in only ~1000 copies in the human genome. Ricksha is a composite transposon that differs from Ricksha_0 by having a ~700-bp insertion of the HERVL endogenous retrovirus including its long terminal repeat (MLT2B). Presumably, the HERVL

provirus was inserted into an active Ricksha_0 copy, which amplified into the Ricksha subfamily. A second family of human MuDR-like transposons was reported recently as the Merlin1_HS autonomous transposon, which encodes a transposase that is the most similar to the IS1016 bacterial transposase. Since the IS1016 and IS256 transposases are distantly related, Merlin1_HS can be considered to be a member of the MuDR superfamily, quite different from standard MuDR transposons. Merlin1_HS is characterized by the 8-bp TSDs and 21-bp TIRs with 5′-GGA and TCC-3′ termini. The human genome harbors fewer than 100 copies of Merlin1_HS. They are ~20% divergent from the consensus sequence, which indicates their activity some 100 million years ago.

4 Repetitive Elements and Human Diseases

The potential pathogenic impact of repetitive elements can manifest itself through a broad spectrum of pathways. The first category of disorders is linked to the expression of active TEs, particularly to the production of proteins. Such proteins can interfere with cellular processes and, most importantly, they can provoke host immune reactions against cells containing TE antigens. The second group of pathogenic effects linked to repetitive DNA includes mutations and genetic rearrangements such as satellite expansion, repeat insertions, deletions, illegitimate recombination, or nucleolytic activity of proteins encoded by TEs. These mutations can occur both in germline or somatic cells.

The pathogenic potential of TE-derived protein products is far from being understood. Relevant research was done mostly on human endogenous retroviruses (HERVs; Sect. 3.1.2). HERVs have been proposed as causative agents of autoimmune diseases such as rheumatoid arthritis, systemic lupus erytrematosus, insulin-dependent diabetes mellitus, and multiple sclerosis. Other potentially HERV-linked disorders include schizophrenia and several types of cancer. In many such cases, retroviral mRNAs or even entire particles were detected in malignant tissues. Retroviral antigens such as the *gag* gene product may indeed trigger immune reaction against affected tissues leading to autoimmune abnormalities. However, it is still unclear whether expression of retroviral mRNAs and proteins causes or merely correlates with the pathological processes. Increased expression of TEs is typical of many cellular alterations including cell transformations. This indicates that rather than inducing the pathogenesis, the expression of TEs may simply reflect relaxed transcription control in malignant cells.

Repeat-induced DNA rearrangements represent a wide range of mutation defects related to the amplification of repetitive elements and genetic recombination. Genetic diseases can be caused by both simple and interspersed repeats. The unstable expansions of simple sequence repeats, namely, trinucleotides, are involved in a number of genetic diseases. The fragile X syndromes (known as FRAXA and FRAXE) involve CGG and GGC triplet expansions. Myotonic dystrophy can be caused by the CTG/CAG repeat expansion. Other examples of diseases associated with moderate expansion of CAG repeats include neural diseases such as Kennedy's disease, Huntington's disease, spinocerebellar ataxia 1 (SCA1) and dentatorubropallidoluysian atrophy (DRPLA). The disease-related triplet expansions are much more frequent than

contractions, and occur primarily in GC-rich genes.

Centromeric and telomeric repeats can also trigger chromosomal instabilities in the human genome. Recombinations between both centromeric and telomeric satellites were reported in cases of chromosome rearrangements, chromosome fragility, or jumping chromosomal translocations.

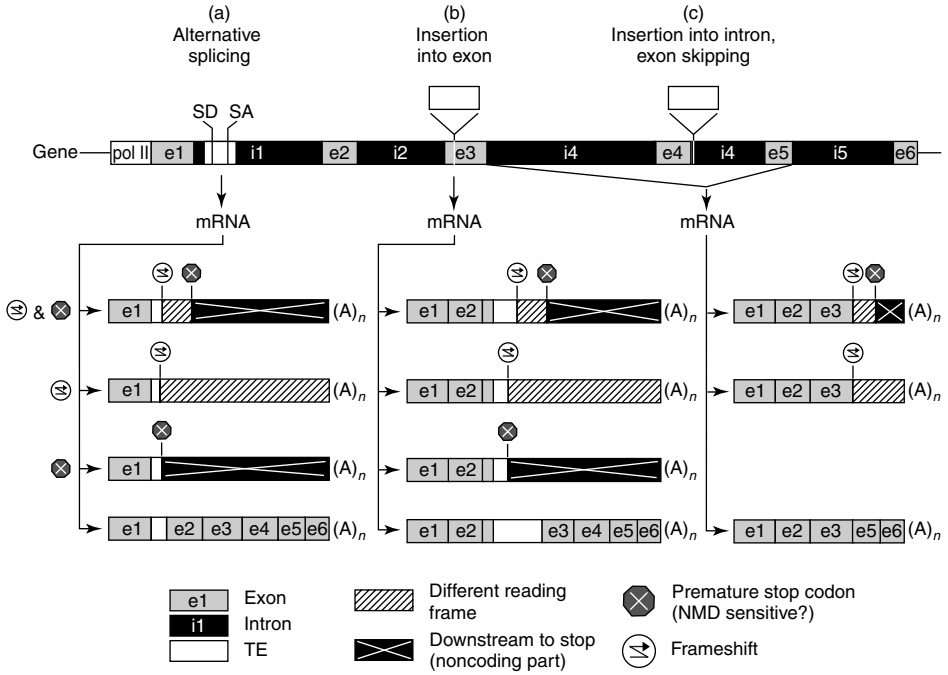

Fig. 13 Transposable elements and human disease. Three different mechanisms of TE-mediated disruptions affecting the gene functionality: (a) intronic repeats that contain splice donor (SD) and splice acceptor (SA) sites, can provide a new exon. (b) Insertion of transposable element into exon. (c) Insertion of transposable element into intron, disrupting proper splicing can lead to exon skipping. All three disruptions lead to similar changes on the mRNA level. Insertion or deletion in coding sequences may change the reading frame, if the indel length is not a multiple of three. Long frameshifts are likely to induce premature stop codon(s) into mRNA (case 1). mRNAs with premature stop codon (i.e. located more than 50–55 bp upstream of the last exon–exon junction) are likely to be destroyed by the nonsense-mediated RNA decay (NMD), and the corresponding protein is not produced. In some cases, particularly for short frameshifts, the random stop codon is found close enough to the last exon–exon boundary and the protein can be synthesized, albeit with an aberrant C-terminal domain (case 2). Note that mRNAs completely lacking stop codons are also destroyed by the cellular RNA control, although by a different pathway than the nonsense-mediated RNA decay. Insertions containing stop codon without change in the reading frame (case 3). Again, if the stop is more than 50 to 55 bp 5′ from the last exon–exon junction, the RNA is likely to be NMD-sensitive and the protein is not produced. Finally, if neither frameshifts nor new premature stop codons are induced, insertions lead to creation of a protein with a new repeat derived domain. Exon-skippings induce deletions of some domains. These new proteins may or may not be functional.

Interspersed repeats can affect alternative splicing and cause inclusion of intronic repeats into cellular mRNAs. This can alter or destroy the mRNA or protein functionality and be manifested as a disease phenotype. Notably, Alu repeats contain cryptic splice sites in the antisense orientation that, after acquiring specific mutations, can give rise to new Alu-derived exons (Fig. 13a). The majority of such Alu cassettes are alternatively spliced and produce premature termination (stop) codons. The affected mRNAs are probably destroyed by cellular mRNA quality control machinery, particularly by the nonsense-mediated RNA decay (NMD) pathway, which degrades mRNAs with premature stop codons at the time of protein translation. However, if the new exon becomes constitutively spliced in, the NMD control prevents efficient translation of the affected mRNA, and thus causes a deleterious phenotype at the protein level. So far, there are two known cases of disease-related Alu splicing into cellular mRNAs. One, reported in a case of ornithine-delta aminotransferase deficiency, was caused by alternative Alu splicing, creating a premature stop codon. In a second instance, a splice-mediated insertion of an Alu sequence in the precursor of alpha 3 type IV collagen mRNA caused autosomal recessive Alport syndrome in the affected patient. The affected proteins were not expressed in either case, despite the fact that the insertion preserved the open reading frame in the second case.

Insertion into genomic DNA is an integral part of the amplification of interspersed repeats. An integration into coding sequences is likely to cause an insertional inactivation of the targeted gene, which subsequently manifests itself as a genetic abnormality. To date, there are 41 published repeat insertions associated with human diseases (Table 9). All the insertions are either L1 elements (14 cases), L1-dependent Alu (23 cases), or SVA elements (4 cases). The Alu and L1 insertions come nearly exclusively from the two active subfamilies AluY and L1-Ta respectively (Table 9). No recent insertions of endogenous retroviruses or DNA transposons have been reported.

From Table 9 it is clear that some genes are overrepresented among insertion targets, particularly coagulation factors VIII and XI and the dystrophin gene. Furthermore, 42% (19 out of 41) of all documented insertions are on chromosome X, which represents only 5% of the human genome. The bias is particularly strong for L1 insertions 11/14 (79%), and less so for L1-dependent nonautonomous Alu and SVA elements, which represent 26% (6/23) and 25% (1/4) of all documented insertions respectively. Chromosome X is present in only one functional copy in both males and females, due to female imprinting (inactivation) of one X copy. Therefore, the X-linked genes are more vulnerable to mutations. The excess of detected insertions on the X chromosome may reflect the detection bias for dominant phenotypes rather than any preferential insertion patterns on this chromosome.

The majority of insertions listed in Table 9 occurred in exons and the remaining intronic insertions appear to have disrupted splicing or other essential signals located within introns. The deleterious effect of intraexonic insertions is mainly due to the incorporation of premature stop codons into the reading frame and mRNA degradation by NMD (Fig. 13b). Other defects can be caused by intron inclusion or exon skipping (Fig. 13a, c), leading to either truncation of the protein or induction of premature stop codons and NMD sensitivity.

Source: The table is based on the updated online database of TE insertions into the human genome (http://www.med.upenn.edu/genetics/labs/kazazian/human.html).

Table 9 compiles both *de novo* insertions, such as in the case of L1-induced Fukuyama muscular dystrophy, and inherited insertions causing familial disorders, such as an Alu insertion into the adenomatosis polyposis coli (APC) gene, causing hereditary desmoid disease. The table also contains one somatic L1 insertion that inactivates APC, indicating that the L1 retrotransposition can take place in both germline and somatic tissues. Most phenotypes caused by insertional inactivations are negatively selected in the population and subsequently eliminated. Nevertheless, in cases of nonessential genes with mild defects, the insertions may eventually become fixed in the population. For example, an Alu insertion seems to have inactivated the CMP-*N*-acetylneuraminic acid hydroxylase (CMAH) in the human lineage after the evolutionary separation of human and chimp, since all primates except humans contain a functional copy of CMAH. In rare cases, insertions may even produce a positive phenotype. For instance, AluYa5 insertion into intron 16 of angiogenesin-converting enzyme (ACE) seems to provide protection against myocardial infarction and age-related macular degeneration, since genotypes without the insertion have a higher incidence of the aforementioned diseases in comparison to individuals having Alu insertion in both alleles.

Table 10 shows a list of the genetic defects attributed to recombination between interspersed repeats. Preliminary indications for linkage between Alu polymorphisms and genetic diseases, based solely on polymorphism studies, are not included. While for some genes only a single case of recombination between interspersed repeats is known, other loci including LDLR, C1NH, alpha-globin, APC, HEXB or MLL represent hotspots for recombinations. Many independent cases of such recombination have been reported. As in the case of insertions, there is a detection bias for recombinations in X-linked genes. Twelve out of 54 (22%) deletion/duplication loci are located on chromosome X.

In mammalian cells, two major recombination pathways exist: *homologous recombination* and nonhomologous end joining, also known as *nonhomologous recombination*. In the great majority of genes listed in Table 10, homologous recombination between TEs was detected, but nonhomologous recombination between one or more TEs was also found in many genes.

The majority of known rearrangements were reported for direct repeats located within or near one gene. While some rearrangements listed in Table 10 are inherited (i.e. passed through germline cells), others occur primarily during mitosis in somatic tissues. This includes many leukemia- or other cancer-related recombinations. Figure 14 shows a model of mitotic intrachromosomal recombination between direct repeats. Unequal sister chromatid exchange produces one duplicated and one deleted copy. Reciprocal intrachromatid exchange, on the other hand, results in one deletion and one circular episomal DNA, which is frequently lost. The mechanism is the same as for the creation of solo LTRs (see Fig. 10). Mispairing and crossing-over between repeats, leading to deletion, have been reported in 54 genes, compared to duplications in only five.

Internal indels can result in altered lengths of the protein, if the reading frame is preserved, or in premature stop codons within the reading frame. Typical outcomes of internal exon/gene deletions and duplications are shown in Fig. 14. RNAs with premature stop codons

Notes: The table represents a significant update of previously published reviews. Each row corresponds to one or several rearrangements affecting the same gene. [1]: There are dozens of cases of Alu involvement in recombination leading to various forms of both acute and chronic leukemias, and related carcinomas. The disorders known to be, at least partially, caused by Alu recombinations are: t(8;16)(p11;p13), t(11;18)(q21;q21), t(2;8), t(14;19), t(9;11), t(14;18), t(11;19)(q23;p13.3), t(10;16)(q22;p13), t(4;11), Philadelphia translocation t(9;22) and variants, 7q22-q34 inversion, and dup(11)(q23). [2]: Nonhomologous Alu recombination. [3]: Nonhomologous recombination between Alu and L1 elements. [4]: Nonhomologous recombination induced by a polyA tail of an Alu element. [5]: Homologous recombination between two HERV15 elements produced duplication of a 780-kb segment on chromosome Y harboring two genes DBY and USP9Y. [6]: Specific deletion of a single Alu monomer in an intronic Alu element, probably by nonhomologous recombination.

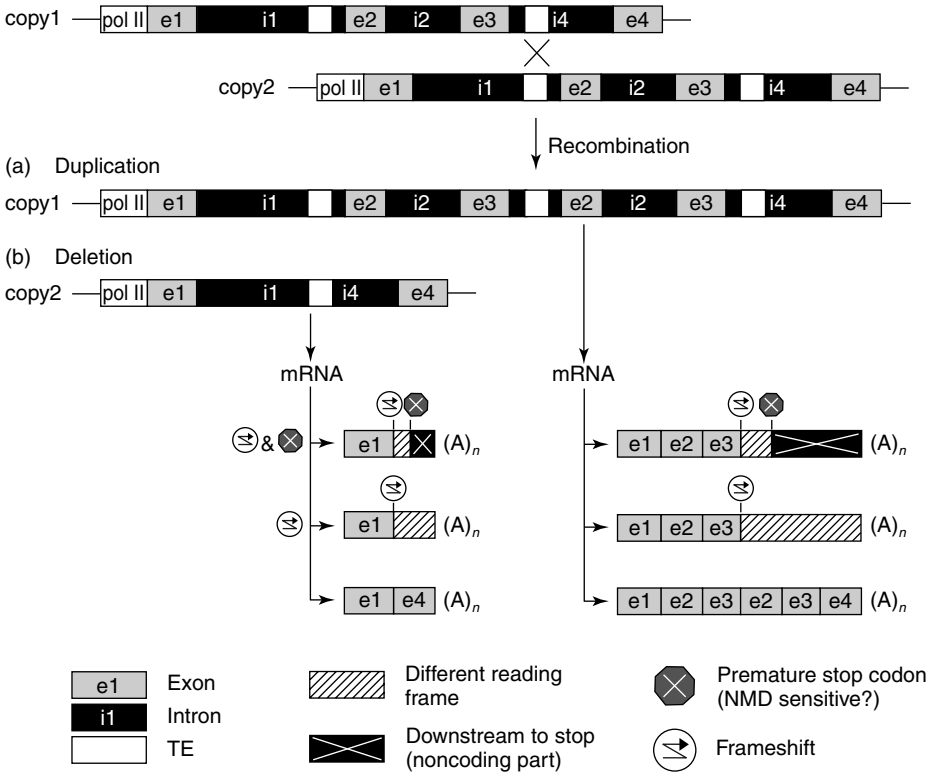

Fig. 14 Recombinations between repetitive elements and human disease. Figure shows classical recombination between two direct intragenic repeats, producing (a) exons duplication; and (b) exon deletion. The effects are similar to those described in Fig. 13.

are likely to be NMD-sensitive, and the resulting phenotype will be manifested by lack of the corresponding protein.

The prevalence of Alu-mediated rearrangements is overwhelming: 55 out of the 61 genes in Table 10 are affected by Alu-induced recombinations. Only three genes with L1 homologous recombinations have been reported so far, and only one case is known for endogenous retroviruses (Table 10). One deletion and one translocation were induced by nonhomologous Alu-L1 recombinations. The excess of detected Alu recombinations is probably related to the Alu genomic distribution and structure. A typical Alu is about 300 bp long, and this size seems to be sufficient for efficient homologous recombination in mammalian cells, where the minimal length requirement is around 150 bp. Alus are by far the most frequent repeats found in human genes. L1 and endogenous retroviruses are underrepresented in GC- and gene-rich regions and are often truncated or rearranged. The rearrangements disrupt the long sequence similarity necessary for homologous recombination. In summary, Alu elements frequently provide closely spaced, highly identical copies prone to recombination in GC-rich and

gene-rich regions, and thus represent the main risk for human genetic disorders caused by recombination between repetitive elements.

Alu sequences contain several regions with elevated occurrence of recombination breakpoints. These include promoters and the AT-rich linker between the left and right Alu monomer. Moreover, Alu elements harbor a 26-bp motif (positions 22–47 at the Alu consensus), possibly associated with increased frequency of recombination. The region contains the pentanucleotide motif core CCAGC, which is also part of chi, and an 8-bp sequence known to stimulate recBC-mediated recombination in *Escherichia coli*.

Alu repeats have also been implicated in the etiology of some recurrent somatic chromosome rearrangements detected in neoplastic tissues. The large-scale rearrangements lead to visible karyotype changes such as Philadelphia translocation, which is associated with chronic myelogenous leukemia. Chromosomal aberrations found in cancers result in loss of heterozygosity and in cancer progression. Apart from somatic translocation, nonlethal cytogenetically balanced chromosomal translocations in germline cells can lead to constitutional congenital disorders. An Alu-mediated translocation, t(9;11)(p23;q23), was shown to cause a familial form of the bipolar affective disorder (manic depression). Also, a patient with translocation t(1;19)(q21.3;q13.2) induced by nonhomologous Alu-L1 recombination was diagnosed with brain atrophy, ataxia, and mental retardation.

Some rearrangements may protect against deleterious changes. For example, the reciprocal translocation t(11;22)(q24;q12) fusing the Ewing's sarcoma (EWS) gene on 22q.12 with the *FLI1* gene on 11q.24, is associated with about 80% of primitive neuroectodermal tumors, including Ewing's sarcoma. However, a 2.4 kb Alu-mediated deletion in ESW intron 6, located near the translocation hotspot, seems to stabilize the region, since the carriers of this allele have a tenfold decreased incidence of EWS compared to populations without the 2.4 kb deletion.

In summary, repetitive elements contribute to human diseases through a variety of mechanisms. While the pathogenetic effects of repeat-encoded mRNAs and proteins are still debatable, repeat insertions and recombinations are significant contributors to genetic variability and abnormalities. The overall frequency of such events is unknown. Typical PCR-based detection of human mutations fails to amplify many large-scale variations, and the resulting defects are likely to be underrepresented in mutation databases. Also, germline recombination producing large rearrangements can terminate embryonic development in early stages, thus providing no opportunity for prenatal diagnostics.

The impact of retrotransposon insertions is small compared with the effect of deletions. Insertions correspond to about 0.1% of all human diseases. Alu-mediated recombinations are estimated to contribute to only 0.3% of human diseases. However, since large rearrangements (about 7.4% of all human mutations) often lack precise determination of breakpoints, it is possible that the impact of Alu recombination is higher.

5 Potential Contribution of Repetitive DNA to Cellular Functions

Satellites and TEs are thought to be involved in a broad variety of processes

directly related to the host cell. They can affect host replication, imprinting, gene silencing, transcriptional and posttranscriptional regulation, alternative splicing, and evolution of genes and proteins. Below are critically reviewed examples of such involvements.

It is believed that alpha satellites are functional elements in human centromeres, and they bind key proteins involved in host replication (see Sect. 2.2.1). However, the complete lack of alpha satellites in *de novo*-created (functional) neocentromeres indicates that they may represent well-adapted selfish DNA.

It has been proposed that L1s may be involved in inactivating chromosome X in female somatic cells. This view is based on the observed overrepresentation of L1 elements on human chromosome X, particularly near the X inactivation center. However, the lack of L1 clusters in the mouse X inactivation center indicates that L1 accumulation near the inactivation start may not be functionally related to the imprinting of the X chromosome.

As mentioned in Sect. 3, TEs contain different transcription regulation sites including promoters, enhancers, and polyadenylation signals. Accordingly, insertions of TEs into regulatory regions may alter the gene expression, and thus they can be negatively selected. For example, the majority of L1 and HERV elements present in introns are in the opposite orientation to the transcription direction of the corresponding genes. The most likely explanation is that polyA signals of these retrotransposons prematurely terminate the transcription if inserted in the direct orientation. Nevertheless, at least some TE-derived polyA signals may be recruited by cellular genes. Pol II transcription signals encoded by endogenous retroviruses and DNA transposons may serve as mobile ''ready-to-use'' blocks involved in the evolution of host genes. In several cases, TE-derived promoters and enhancers are incorporated into human genes. However, repetitive elements are found in many genomic regions, including promoters. Therefore, repeats present in these regions may be tolerated rather than being functional.

Potentially important regulation of genes by TEs may also occur at the RNA level. Antisense transcripts from promoter regions of TE inserted into introns can inhibit gene expression. For instance, a HERV-K element inserted into intron 9 of complement C4 gene in the orientation opposite to the gene transcription produces an antisense mRNA modulating the gene expression. Transposable elements are frequently found in untranslated regions of many mRNAs. Therefore, these mRNAs can also be regulated by transcripts derived from other similar copies of genomic TEs. Expressed SINE sequences can be acquired by the host as novel RNA genes. Indeed, *BC200*, a small RNA gene expressed in the primate brain, is the best-studied example of an Alu element recruited by the genome.

Protein-coding TEs can also be recruited as host protein-coding genes. Table 11 lists examples of TE-derived genes present in the human genome. Well-known examples of such genes are V(D)J recombinase and syncytin. V(D)J recombinase, which catalyzes rearrangements of immunoglobulin and T-cell receptor genes in lymphocytes, shares enzymatic characteristics with mariner/Tc1-like DNA transposases. Syncytin, a cell-fusion protein probably participating in placental morphogenesis and antiviral defense, was derived from the *env* gene encoded by the HERV17 (HERV-W) retrovirus. While the V(D)J

recombinase is an ancient gene, possibly derived from the DNA transposase ~400 million years ago, syncytin is less than 5 million years old. Some host proteins listed in Table 11, like syncytin and Jerky, are entirely derived from proteins encoded originally by TEs. The remaining protein-coding genes were formed by the fusion of the preexisting host proteins with transposon-encoded proteins. Such fusions might have been initiated by alternative splicing.

DNA transposons are most abundant among recruited genes, despite their relatively low abundance in the genome compared to other TEs (Table 11). Rtl1 is the only clear example of RT recruited in the host gene. Genes derived from DNA transposase are probably involved in specific DNA binding and cleavage (e.g. the V(D)J recombinase). Surprisingly, eight genes are derived from Gypsy-like LTR retrotransposons, whose remnants are otherwise not detectable in the human genome. Two genes are derived from *env* genes encoded by HERV-W and HERV-R elements. Proteins from *env*-derived genes may prevent retroviral infections by saturating the cellular receptors for exogenous retroviruses.

The extent of the contribution of TEs to the host protein-coding capacity is still not well known. The number of well-supported examples of TE-derived host proteins is relatively small (Table 11). On the other hand, analyses of human mRNA sequences disclosed several hundreds of mRNAs with one or several exons derived from TEs. However, some of these TE-containing sequences can represent common contaminations in EST libraries. In addition, many of the transcripts contain short reading frames, indicating that they do not code for functional proteins. Indeed, it should be noted that the majority of cellular polymerase II transcripts do not code for any proteins and never reach the cytoplasm. Cellular mRNA control mechanisms such as the nonsense-mediated RNA decay protect cells from potentially pathogenic truncated or aberrant proteins. Indeed, products of TE-containing transcripts are seldom detected at the protein level.

In conclusion, while there are a few well-documented examples of novel functional genes derived from TEs, the extent of this phenomenon is unknown. Many proteins deposited in public databases are hypothetical ORFs predicted by statistical methods based on computational analysis of genomic DNA and/or cDNA sequences. These methods are less than 90% accurate and, as a result, they may include TEs in erroneously predicted proteins. Analogously, databases of sites involved in transcription regulation may include regions whose ''regulatory'' effects are shown *in vitro* only.

6
Databases and Programs for Analysis of Repetitive DNA

About half of the human genome is composed of various repetitive elements. Detection of repetitive elements is a basic step in many biologically important analyses, including, but not limited to, sequence assembly during genome sequencing, genome annotation, similarity searches, and gene and coding sequence prediction. Therefore, specialized tools and databases have been developed for the detection and masking of repetitive elements.

6.1
Databases of Repetitive Elements

The first database of human repetitive elements, Repbase, was published in 1992. Currently it contains over 620 families and subfamilies of human repeats. Repbase became a regularly updated general database of eukaryotic repetitive elements, renamed as Repbase Update (RU). RU is accompanied by the monthly online journal Repbase Reports, which publishes newly discovered eukaryotic repeats.

Currently, RU is released in the EMBL and Fasta formats. Only the EMBL format contains a detailed description and annotation of every RU consensus sequence. In addition, a version of RU manually tailored for RepeatMasker is available. RU contains several sections dedicated to separate eukaryotic species. Human TEs are listed in the section ''humrep.ref.'' Most of the abundant processed pseudogenes can be obtained from the ''pseudo.ref'' library. The ''simple.ref'' library contains the most common simple repeat motifs.

Apart from Repbase Update, there are other useful online resources for studies of human repeats. Table 12 lists selected databases as well as related resources devoted to human repetitive elements.

6.2 Programs for Detection and Analysis of Repetitive DNA

There are two basic approaches for detection of repetitive elements in biological sequences. The first is based on the detection of similarity with previously known repeats. The second *de novo* approach is based on a

Tab. 12 Databases of human repeats, and related sources.

Database	*URL description*
Repbase Update	http://www.girinst.org/Repbase_Update.html *De facto* the only specialized database of eukaryotic repetitive elements. To date, Repbase Update contains consensus sequences and annotation for more than 4000 different eukaryotic repetitive elements. The content can be searched through sequence similarity search on the Censor web server, or through the text search using keywords.
HERVd	http://herv.img.cas.cz/ The Database of Human Endogenous Retroviruses (HERVs) maps all known endogenous retroviruses in the human genome. Retroviruses can be searched using several criteria such as family, length, chromosome etc., or by fasta similarity search. Several characteristics including the GC content, CpGs are calculated.
Human TE Insertion	http://www.med.upenn.edu/genetics/labs/kazazian/human.html The database lists known insertions of repetitive elements into the human genome associated with human genetic diseases.
Exapted retrogenes	http://www-ifi.uni-muenster.de/exapted-retrogenes/tables3.html Examples of vertebrate regulatory elements, parts of coding regions or genes generated by retroelements. Vertebrate genes generated by retrosequences.
UCSC GoldenPath	http://genome.ucsc.edu/ The UCSC human genome assembly contains extensive annotation files including tables with maps of repetitive elements in the human genome.
Ensembl	http://www.ensembl.org/ The ensembl genome assembly contains extensive annotation files including tables with maps of repetitive elements in the human genome.

search for characteristic properties of particular repeats. Table 13 lists some of the most popular programs developed for the detection of repetitive elements.

Similarity-based methods typically compare a library of known repetitive sequences against genomic DNA using general programs for sequence similarity search such as blast, wublast or cross_match. The repetitive library can be any custom set of repeats; however, specialized programs nearly exclusively rely on consensus sequences from Repbase. *De novo* detection methods do not require prior knowledge of repeats and the guiding principle of this approach is to search for the presence of multiple copies in the genome.

Standard detection programs for interspersed repeats use similarity-based detection of repeats. Censor and MaskerAid require wublast, while RepeatMasker uses the Smith-Waterman algorithm implemented in cross_match. For large quantities of data or for quick searches, it is better to use Censor or

Tab. 13 Programs for detection of repetitive sequences in biological sequences.

Program (package)	***URL description***
Censor	http://www.girinst.org/Censor_Server.html General package for similarity-based identification of interspersed and tandem repeats in both nucleic and amino acid sequences. Requires wublast and Repbase Update repeat libraries. Both online and local versions are available.
RepeatMasker	http://ftp.genome.washington.edu/cgi-bin/RepeatMasker General package for similarity-based identification of interspersed and tandem repeats in nucleic acid sequences. Requires cross_match and Repbase Update repeat libraries. Both online and local versions are available.
MakerAid	http://sapiens.wustl.edu/maskeraid/ Program performs a similarity-based detection of interspersed and tandem repeats in nucleic acid sequences. Can be used with RepeatMasker for fast repeat identification. Requires wublast and external repeat libraries. Local versions only.
Tandem repeat finder	http://tandem.biomath.mssm.edu/trf/trf.html An excellent program to for *de novo* detection of tandem repeats in DNA sequences. Both online and local versions available.
Satellites	http://bioweb.pasteur.fr/seqanal/interfaces/satellites.html Program to for *de novo* detection of tandem repeats in DNA sequences. Online version only.
Sputnik	http://espressosoftware.com:8080/esd/pages/sputnik.jsp Scans for 2–5 long tandem repeats using *de novo* search.
EMBOSS	http://www.hgmp.mrc.ac.uk/Software/EMBOSS/index.html A general open source package for analysis of biological sequences. Two included programs etandem and equicktandem detect tandem repeats using *de novo* search. Local versions only.

MaskerAid, since they are much faster than cross_match-based RepeatMasker. RepeatMasker and MaskerAid are restricted to nucleic acid sequences only. Censor, on the other hand, can perform virtually any similarity search implemented in the wublast package, including translated searches, and can even detect repetitive elements in protein sequences. All these programs produce maps of repetitive elements in query sequences, with the exact position of each repeat. These three programs also ''mask'' sequences, that is, they replace detected repeats by special characters, usually by ''N'' for nucleic and ''X'' for protein sequences. Such masking is essential for many database searches or gene predictions. Moreover, all these programs detect the most frequent simple repeats.

Unlike in the case of interspersed repeats, *de novo* detection is the primary approach in the analysis of simple repeats. There are several packages for the detection of microsatellites with short unit sizes, but for minisatellites with large units there are only a few suitable programs. In such situations, Tandem Repeat Finder can be applied.

In summary, for routine detection of known repeats it is best to use Censor, RepeatMasker, or MaskerAid with appropriate repeat libraries (Repbase Update libraries). These programs also detect the majority of simple sequence repeats, particularly the most abundant microsatellites. Specialized analysis of simple sequence repeats may involve specialized *de novo* detection programs. The majority of programs listed in Table 13 can be installed only on Linux/Unix-related systems. Users of other operating systems may use several programs that have online submission forms, as specified in Table 13.

Keywords

Spore
A dormant, protective form that certain bacteria can take to help them survive adverse conditions.

Phagosome
Cellular compartments formed when cells engulf large particles, such as bacteria, from their environment.

Endocytosis
The process by which cells take up material from their environment. This involves membrane invagination and the formation of an internal membranous compartment called an *endosome*.

Transposon
A mobile genetic element that is able to insert a copy of itself into a chromosome or plasmid.

Virulence Factor
A factor that helps a pathogen cause disease.

Regulon
A set of genes whose expression is regulated in a coordinated fashion.

Abbreviations

PA	Protective antigen
EF	Edema factor
LF	Lethal factor
AFLP	Amplified fragment length polymorphism
MLVA	Multiple-locus variable-number tandem repeat analysis
LR REP PCR	Long-range repetitive element polymorphism-PCR
VNTR	Variable-number tandem repeat

Bacillus anthracis, the causative agent of anthrax, has been a subject of research for over 150 years, beginning with the work of Rayer and Davaine who found ''small filiform bodies'' in the blood of anthrax-infected sheep and, from this finding, coined the term *bacteria*. Several years later, Koch proved conclusively that *B. anthracis* was the causative agent of anthrax, providing the first demonstration that a disease was

caused by a specific bacterium. He later developed the first live attenuated bacterial vaccine with a heat-attenuated strain of *B. anthracis*. Despite its illustrious beginnings as a subject of research, an understanding of the molecular biology of *B. anthracis* has lagged behind that of some other bacteria. *Bacillus anthracis* has recently come back into focus as a target of research with the goal of being able to readily detect this bacterium in environmental samples and to understand its pathogenesis and evolution better.

1 Anthrax

Bacillus anthracis is a gram-positive, spore-forming bacterium that normally resides in the soil, but when taken up into the body, causes anthrax. This facultative aerobe grows on many types of culture media and its colonies appear mucoid and are not generally hemolytic. Upon microscopic examination, chains of encapsulated, nonmotile, rod-shaped bacteria are seen. For infection to occur, spores of *B. anthracis* may be taken up through one of three routes: inhalation, ingestion, or via an abrasion of the skin. From there, the spores are engulfed by macrophages and carried to regional lymph nodes. Spore germination in macrophages appears to be required for the establishment of disease, and the spores require this intracellular environment to stimulate germination. It has been shown that, at least in culture, the newly vegetative bacilli escape the phagosome to reach the cytoplasm of macrophages, where they multiply and are eventually released into the extracellular environment. Macrophages, therefore, end up playing a major role in the pathogenesis of *B. anthracis* because they provide an appropriate environment for spore germination and they also provide a transportation route that gives the bacteria access to the blood stream where high levels of bacteremia can ensue. Once this stage is reached, a shock-like syndrome and death follow; although this severe disease course is usually associated with inhalation or gastrointestinal anthrax, a cutaneous anthrax infection is generally contained prior to the achievement of bacteremia.

The majority of *B. anthracis* strains carry two large virulence plasmids, called pXO1 and pXO2. Both plasmids are required for full virulence. pXO2 carries the *cap* region, an operon encoding a poly-D-glutamic acid capsule that helps the bacteria evade the immune system by allowing them to resist phagocytosis. The other plasmid, pXO1, carries *pagA*, *lef*, and *cya*, the genes encoding the three components of the anthrax toxin: protective antigen (PA), lethal factor (LF) and edema factor (EF) respectively. The symptoms of anthrax are largely mediated by this toxin. In fact, an anthrax infection can be fatal even after the blood has been cleared of all *B. anthracis* owing to the toxin that has already been released into the body.

The toxin proteins work in binary combinations to produce toxic effects; PA is the carrier molecule that delivers the enzymatic portions of the toxin, EF and LF, to the cytosol of cells. There, EF, an adenylate cyclase, increases cAMP levels, which are presumed to play a role in the development of the

pulmonary edema and tissue swelling that are seen with anthrax infections. LF, on the other hand, appears to alter the production of cytokines by macrophages and to induce macrophage lysis. It is a zinc-dependent metalloprotease that cleaves MAP kinase kinases, leading to apoptosis of the cells through inhibition of an antiapoptotic signaling pathway that involves p38 MAP kinase. LF gets its ominous name from the fact that coinjection of PA and LF, even in the absence of any *B. anthracis*, is sufficient to kill an animal.

Briefly, the intoxication process, as we currently understand it, occurs as follows (Fig. 1): PA binds to a ubiquitous receptor, named *anthrax toxin receptor* (ATR), on mammalian cells. A 20-kD amino-terminal piece of PA is then cleaved off the protein by a furin-like protease, leaving the remaining 63-kD carboxy-terminal portion of PA (PA63) bound to the receptor. This proteolysis, also called *nicking*, facilitates the organization of PA63 into a seven-membered ring-shaped structure, reveals the binding sites for EF and LF, and stimulates endocytosis of the PA-LF and PA-EF complexes. The toxin complexes are trafficked to endosomal compartments, wherein low pH triggers the PA63 ring to insert into the endosomal membranes as a protein channel. Through a mechanism that involves unfolding of EF and LF, the PA63 channel delivers its ligands to the cytosol of the intoxicated cells, where they exert their enzymatic effects.

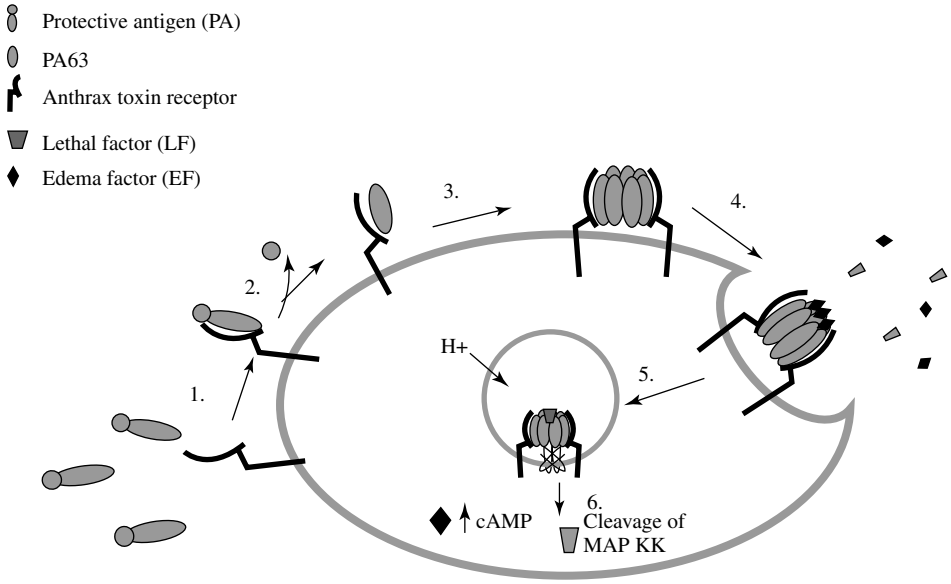

Fig. 1 Cellular intoxication cycle for anthrax. Step 1. PA binds to the anthrax toxin receptor. Step 2. PA is nicked, removing a 20-kD amino-terminal portion of the protein and leaving PA63 bound to the receptor. Step 3. Seven PA63 molecules come together to form a ring-shaped heptamer. Step 4. The PA63 heptamer binds EF or LF. Step 5. The toxin complex is endocytosed. Step 6. In response to a drop in pH in the endosomal compartment, the PA63 heptamer forms a membrane channel that mediates the translocation of EF and LF to the cytosol of cells, where they exert their enzymatic effects.

2 The Virulence Plasmids

A gapped, linear sequence of approximately 93 kbp has been generated for pXO2, but a detailed analysis of the sequence has not yet been published. Comparison of the pXO2 sequences from various *B. anthracis* isolates identified several variable pXO2 markers, leading to the suggestion that this plasmid is the source of much of the variability in the *B. anthracis* genome. More work needs to be done before the functions of the gene products encoded by this plasmid are discovered.

The 181-kbp pXO1 plasmid has been fully sequenced. It has 143 predicted open reading frames, most encoding proteins of unknown function. There are also several pXO1-associated phenotypes that have not been assigned to a particular gene. Among these phenotypes are different nutritional requirements, altered sensitivity to bacteriophages, and escape of *B. anthracis* from cultured macrophages.

The most striking feature of this plasmid is a 44-kbp region that has been designated a pathogenicity island (Fig. 2). These islands are large regions of DNA that confer virulence phenotypes and are believed to have been acquired from unrelated organisms. The pathogenicity island of pXO1 contains 31 predicted open reading frames, including all three toxin genes and their regulatory elements. It is flanked by two inverted and nearly identical copies of an insertion sequence element that serve as footprints for previous transposition of DNA. Also, within the island are genes encoding transposases and integrases – enzymes that are involved in the movement of DNA segments – which, along with the insertion sequences, suggest that there may be plasticity to this region. In fact, comparative restriction analysis of this region in different *B. anthracis* isolates indicates that the pathogenicity island is inverted in some strains.

The origin of this pathogenicity island is unclear, if, in fact, it did come from another species. One possibility is that it came from a member of the *Bacillus cereus* phylogenetic group, to which *B. anthracis* belongs, as some of the insertion sequence elements in the pathogenicity island are very similar to those isolated from other members of this group. Further supporting this hypothesis is the fact that the GC content of the pathogenicity island does not differ significantly from that of the rest of

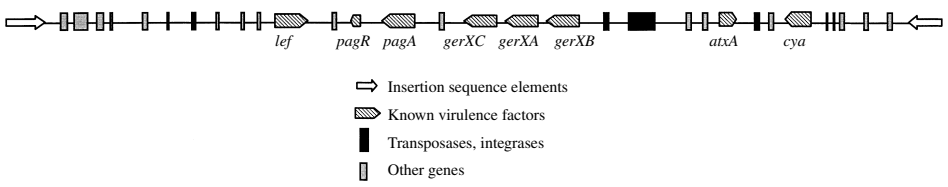

Fig. 2 The pathogenicity island of *B. anthracis*. Depicted is the basic structure of the pathogenicity island that is located on the pXO1 plasmid. It encodes, among other things, a major virulence gene regulator (*atxA*), the anthrax toxin proteins (*pagA*, *lef*, *cya*), and an operon involved in sporulation (*gerXA*, *gerXB*, and *gerXC*). Adapted from Okinaka, R.T., Cloud, K., Hampton, O., Hoffmaster, A.R., Hill, K.K., Keim, P., Koehler, T.M., Lamke, G., Kumano, S., Mahillon, J., Manter, D., Martinez, Y., Ricke, D., Svensson, R., Jackson, P.J. (1999) Sequence and organization of pXO1, the large *Bacillus anthracis* plasmid harboring the anthrax toxin genes, *J. Bacteriol.* **181**, 6509–6515.

pXO1 or the *B. anthracis* genome, nor is there a difference in codon usage between them, so the pathogenicity island must have evolved in a species very similar to *B. anthracis*.

In fact, other members of the *B. cereus* group possess many sequences related to the pXO1 coding sequences. A recent hybridization study found that DNA from three members of this group (two *B. cereus* strains and a *Bacillus thuringiensis* strain) each hybridized with over half of the probes that were used to represent the pXO1 open reading frame complement. This conservation of pXO1 genes is independent of evolutionary relatedness in terms of the chromosomal sequences, further supporting the idea that these sequences may shuffle between related species.

Lest the reader fear that the deadly anthrax toxin genes are jumping around between bacteria, I will point out that approximately 20% of the open reading frames tested in this study, including those encoding the anthrax toxin, were not found in any of the related species that were tested, and are, as far as we know, unique to anthrax. Further, the results of a phylogenetic analysis of *pag* sequences from several *B. anthracis* strains largely agreed with those from a similar analysis of chromosomal sequences. This suggests that the *pag* gene did not evolve separately from the chromosome, so this gene probably did not undergo horizontal transfer during the recent evolution of *B. anthracis*.

3 Molecular Identification of *B. anthracis*

Standard microbiological techniques can be used to distinguish *B. anthracis* from other bacilli. Distinguishing characteristics include lack of motility and hemolysis, a typical colony morphology (including a flat, tacky appearance and gray-white color), and susceptibility to lysis by gamma phage. Although these techniques can be used to identify *B. anthracis* in most cases, the threat of bioterrorism makes the development of rapid molecular surveillance methods, for use in environmental samples, a priority. Microbiological techniques rely upon isolation and culture of bacteria, and they generally take at least 24 h to complete. This fact can limit their successful use in certain situations. It would be desirable to develop faster diagnostic methods so that anthrax outbreaks can be identified and managed as rapidly as possible. A second limitation to standard microbiological techniques is the fact that anthrax victims who are treated with antibiotics before blood cultures are taken often have blood cultures that are negative for *B. anthracis*. For accurate diagnosis of these patients, molecular diagnostic techniques must be perfected.

As mentioned above, *B. anthracis* is genetically closely related to *B. cereus* and *B. thuringiensis* and, in fact, some researchers have proposed on the basis of multilocus enzyme electrophoresis as well as 16S and 23S rRNA sequence analysis, that these organisms be classified as subtypes of the same species. The relatedness of these bacteria has complicated efforts to develop *B. anthracis*-specific tests because the detection of related species as false-positives can be a problem.

3.1 Molecular Methods to Distinguish *B. anthracis* from Other Bacteria

The presence of virulence plasmids, including pXO1 and pXO2 in *B. anthracis*,

is the primary characteristic used to distinguish *B. anthracis* from related bacilli. However, it has been demonstrated experimentally that plasmids can be transferred between *B. cereus, B. thuringiensis,* and *B. anthracis.* Further, there are naturally occurring isolates of plasmidless *B. anthracis,* so a method to distinguish chromosomal DNA is important. Because the genomes of *B. anthracis* and *B. cereus* are estimated to share 98% DNA sequence homology, identification of unique diagnostic markers will be important for the definitive identification of the related strains. In the following section, several genetic sequences that have been purported to be unique to *B. anthracis* will be discussed, as will their usefulness in the identification of this species.

Ba813 was the first locus that was proposed as a unique marker for *B. anthracis.* A PCR assay for the detection of this chromosomal DNA fragment was proposed as a reliable method to detect this species. Subsequent studies found the Ba813 marker in other bacilli, so this marker alone does not appear to be sufficient to distinguish anthrax from environmental samples. The relationship of the Ba813-carrying, nonanthrax *Bacillus* strains to verifiable *B. anthracis* is not yet clear. Genetically, these strains are closely related to each other but distinct from *B. anthracis.*

Other assays for specific chromosomal regions have been developed, including one for variability in *rpoB,* which is almost exclusively found in *B. anthracis* strains. Interestingly, the one exception to this was a nonanthrax *Bacillus* strain that also carried Ba813.

A variable region in the *B. anthracis* chromosome has been identified using arbitrarily primed PCR. Only one complete open reading frame was present in this region, and it was dubbed *vrrA,* for variable region with repetitive sequence. PCR of this region amplified a fragment of distinct size from *B. cereus, Bacillus mycoides,* and *B. anthracis,* allowing these closely related species to be distinguished from each other. Although most of this variation was located in *vrrA,* many of the single nucleotide substitutions that differed between *B. anthracis* and the other bacilli were third position synonymous mutations that would not change the encoded amino acid sequence. The role of the *vrrA*-encoded protein is unknown, but the gene most closely resembles *shp2,* a gene that encodes a sheath protein in microfilarial parasites. A repetitive sequence, QYPQ, in the parasite protein is also predicted in the *vrrA*-encoded protein, and this sequence has been implicated in the covalent cross-linking of multiple protein subunits.

Rather than looking at one locus at a time, a more effective method of distinguishing *B. anthracis* from related species is to use techniques that look at multiple loci simultaneously. One of the methods that has been used is amplified fragment length polymorphism, or AFLP. In this method, restriction fragments of DNA from the test sample are ligated to linker fragments that are then used to prime an amplification reaction (Fig. 3). The labeled primers used in this reaction can be made more or less specific, so that a manageable number of fragments are produced in the final output. These amplified fragments can then be screened for length polymorphisms using gel electrophoresis, with the idea that there will be a species-specific pattern of restriction polymorphisms.

AFLP has the advantage that a large number of loci are examined at once and that no prior knowledge of the

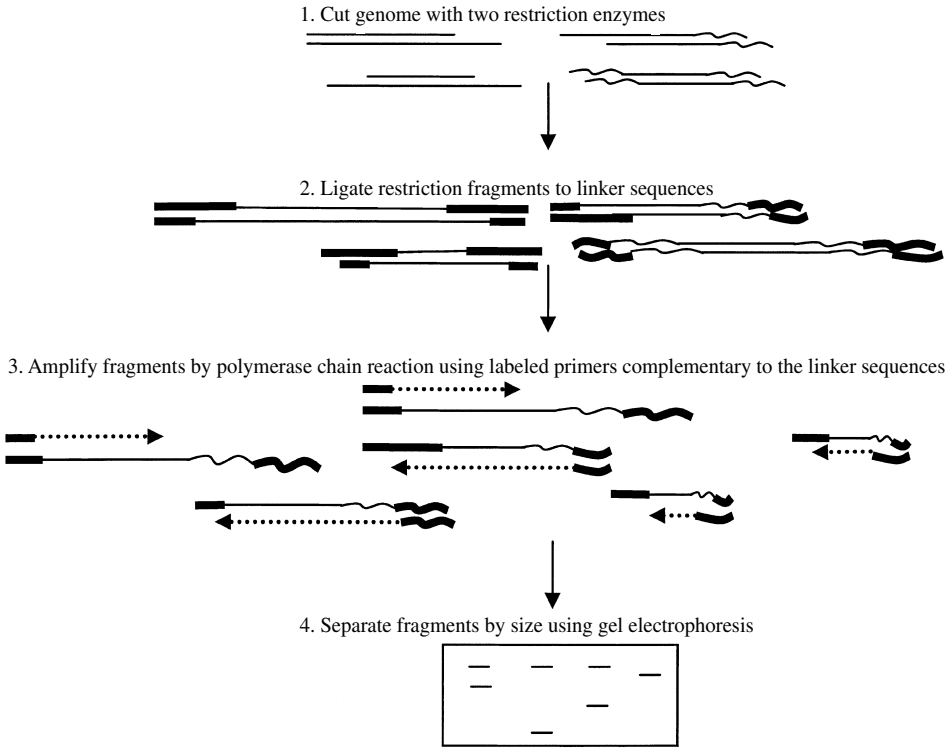

Fig. 3 The basic method for AFLP analysis. In this method, DNA from a sample is cut into pieces using restriction enzymes. The size of these fragments should differ between samples, based on the location of restriction enzyme sites in the DNA sequences. Rather than amplifying the DNA restriction fragments using sequences within them, linkers of known DNA sequence are attached to the ends of these fragments so that they may be amplified using primers complementary to the linker fragments. This allows one to amplify DNA even when the sequences in the target organism are unknown. The amplified fragments can then be separated by size so that the patterns of fragments between samples can be compared.

genetic makeup of the target organism is necessary. The AFLP profile of a sampled organism can be compared to that of known profiles for identification. These comparisons can be logistically difficult, especially when a large number of fragments are examined at once. To make this easier, AFLP profiles for a number of organisms are being archived and algorithms developed to automate these comparisons. This method does show promise for use in the identification of *B. anthracis*, because the AFLP profiles generated for a variety of *B. anthracis* strains show significant differences from closely related *Bacillus* species.

Long-range repetitive element-polymorphism PCR (LR REP-PCR) is another method that uses length polymorphisms to distinguish between bacterial species. This technique uses highly conserved repetitive extragenic palindromic (REP) sequences in DNA as target sequences in a PCR reaction. DNA sequences that lie between two adjacent REP sequences are amplified in these reactions (Fig. 4).

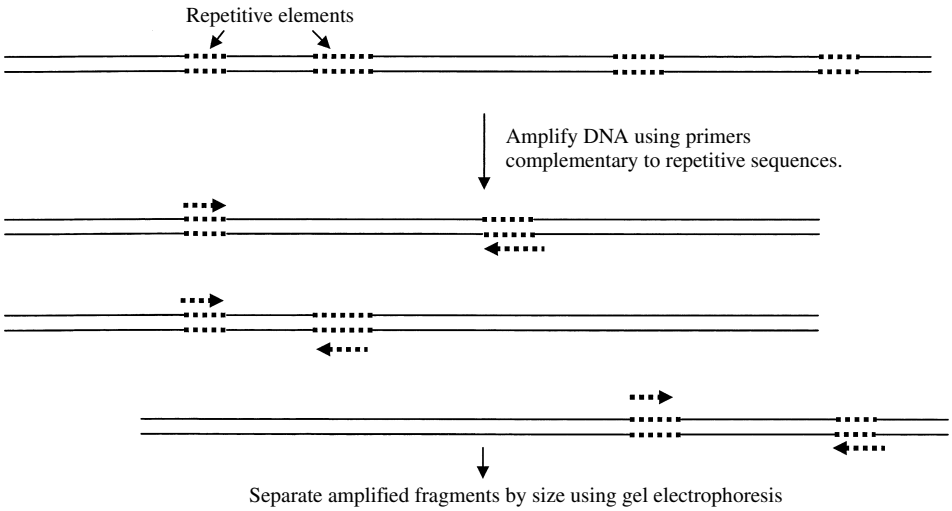

Fig. 4 Long-range repetitive element polymorphism-PCR (LR REP-PCR). Certain sequences occur many times within a bacterial genome, and these are called repetitive elements. The number and location of these REPs will vary between bacterial species. One can use primers complementary to the REPs to amplify fragments of DNA that will vary in size depending on the spacing of the REPs in the genome. As with AFLP, these fragments can be separated by size using gel electrophoresis and the patterns of fragments can be compared between samples.

PCR fragments of different size will be amplified in different strains, depending on the spacing of REPs in each. This technique clearly distinguishes between *B. anthracis* and related *Bacillus* species.

Another method that is proving useful for the identification of *B. anthracis* is multiple-locus variable-number tandem repeat analysis (MLVA). Variable-number tandem repeat (VNTR) loci are short, repeated sequences of DNA that vary in copy number, thereby creating a length polymorphism that can be detected by PCR amplification of fragments in the region. Because of their greater diversity, these markers have more power to discriminate between species of bacteria than other molecular typing methods. Most of the MLVA primers developed for *B. anthracis* do not amplify sequences from related *Bacillus* species, so this method appears to be useful in distinguishing *B. anthracis* from closely related species.

3.1.1 Post-October 2001 Research

Research efforts aimed at understanding and detecting anthrax have been ramped up since the intentional release of anthrax in 2001. This research has covered everything from epidemiologic surveillance, to methods of sample collection during an investigation, and to rapid methods for the detection of anthrax during a potential outbreak. The following section provides a discussion of the technologies that were found to be useful in the detection of anthrax.

The sequence of the 16S rRNA gene is often used to identify unknown bacteria. Owing to the similarities between the 16S rRNA sequences of *B. anthracis* and its relatives, it was thought that this

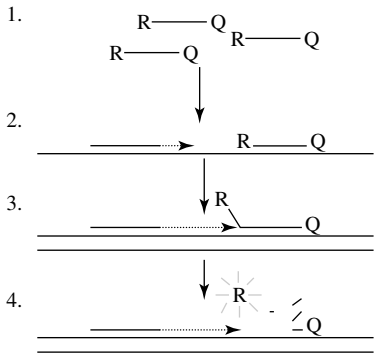

Fig. 5 5′ nuclease real-time PCR assay. 1. A probe complementary to the target sequence is labeled with a fluorescent reporter (R) and a quencher (Q). At the beginning of the reaction, the close proximity of these molecules allows the quencher to act on the reporter and little fluorescent signal can be detected. 2. As the target sequence is amplified, the probe binds to it. 3. The Taq DNA polymerase in the reaction uses its 5′ to 3′ nuclease activity to degrade the probe. 4. As the probe is degraded, the reporter and quencher separate and the quencher no longer acts on the reporter, leaving it free to fluoresce. This signal is used as a measure of the amount of probe that has been degraded, which is directly related to the amount of target sequence in the reaction.

analysis would not be useful for the identification of *B. anthracis*. However, this conclusion was based on a limited number of 16S rRNA sequences. During the investigation of the outbreak, the 16S rRNA sequences from a number of *B. anthracis, B. cereus*, and *B. thuringiensis* strains were determined, and it was found that, indeed, it was possible to distinguish between the species. All bacillus strains in this study, including 86 *B. anthracis* strains, possessed 16S rRNA types that were unique to their species. In Genbank, there are, however, 3 16S rRNA sequences from *B. anthracis* that fall into a type that was exclusively found in *B. cereus* in this study. The explanation for this discrepancy is unclear at this point, and it may be due to a methodological or an actual biological difference.

Real-time PCR has also proven effective for the rapid identification of anthrax. The method that has been used is a 5′ nuclease assay, which exhibits increased sensitivity compared to a traditional PCR method (Fig. 5). In addition to primers, 5′ nuclease assays use a fluorescently labeled probe that is complementary to the target sequence. This probe is labeled with a reporter fluorophore as well as a quencher for this reporter. When the probe is added to the reaction, the quencher and reporter are in close proximity and little fluorescent signal is detectable. However, as the target sequence is amplified and the probe binds to it, the 5′ to 3′ exonuclease activity of the Taq polymerase in the reaction degrades the probe, releasing the reporter fluorophore from its quencher and leading to an increase in the fluorescent signal. In the case of *B. anthracis*, three primer and probe sets were used; one each to detect pXO1, pXO2, and the *B. anthracis* chromosome. All fully virulent *B. anthracis* strains tested were positive for all three targets, yielding 100% sensitivity for virulent bacteria. Further, none of the non-*Bacillus. anthracis* strains, including *B. cereus* and *B. thuringiensis*, tested positive for all three targets, giving 100% specificity, as well. The lower limit of detection with this assay is estimated to be 1 pg of DNA or approximately 5 to 10 spores. *B. anthracis* strains lacking one or the other virulence plasmid

will obviously not test positive in all three reactions, and additional methods will need to be used to confirm their identity.

Some anthrax detection methods look for actual bacteria rather than for DNA. One such method is a *fluorescent antibody assay* that has also been validated for rapid identification of *B. anthracis*. In this method, two fluorescently labeled monoclonal antibodies, one against the cell wall polysaccharide antigen and one against the capsule antigen, are incubated with bacterial samples. The cells are then washed to remove unbound antibody and scored under a fluorescent microscope. Although other bacillus strains express a similar polysaccharide antigen, these bacteria lack the poly-D-glutamic acid capsule and will not score positive with both antibodies. The combined assay was 99% specific, with 227 of 230 *B. anthracis* isolates scoring positive, and 100% specific, with none of the 56 non-*Bacillus anthracis* strains scoring positive. It also could provide results within 3 to 6 h. Several clinical samples that were positive for *B. anthracis* by the real-time PCR assay were not detected by this fluorescent assay, so the latter assay may not be as sensitive. However, the antibody assay requires less lab space and sophisticated equipment and, therefore, may be useful in an outbreak situation, especially as a rapid confirmatory assay.

A method that may be useful for the detection of exposure to *B. anthracis* in clinical samples is an enzyme-linked immunosorbent assay (ELISA) that detects antibodies to PA. Only individuals who have been exposed to or vaccinated for anthrax will show positive results in this assay. In this ELISA, recombinant PA is bound to a microtiter plate. Serum from the test subject is then added to the plate and incubated to allow anti-PA antibodies from the serum to bind to the plate. Following extensive washes, an antihuman IgG antibody labeled with a reporter molecule is used to measure the amount of anti-PA antibody bound to the plate. The specificity of this assay can be enhanced through competitive inhibition, where test sera are incubated in the presence or absence of excess recombinant PA in solution before analysis in the standard ELISA. If the antibodies detected in the ELISA are truly specific for PA (and not just sticking to something in the assay nonspecifically), they should be removed from the assay by this competitive inhibition, and little antibody will bind to the microtiter plate. This assay will be used as part of a panel of tests for the confirmation of clinical human anthrax. This test should not be used as the sole confirmation of anthrax because it is known that, at least in nonhuman primates, early antibiotic treatment of an anthrax infection can abrogate the development of anti-PA antibodies.

3.2 How do You Tell One Strain from Another?

Not only is it important to be able to distinguish *B. anthracis* from related *Bacillus* species, it has also become important to distinguish between different strains of *B. anthracis*. This is important for tracking the history of an environmental outbreak and in the investigation of acts of terrorism that use *B. anthracis*. It has been difficult to develop methods to distinguish between *B. anthracis* strains because this is one of the most monomorphic species known – which means that it has very little genetic variation. Of 1221-AFLP fragments examined in 79 *B. anthracis* isolates in one study, 97% were monomorphic – no sequence variation was found between the

isolates. Looking at a specific gene important for virulence, Price et al. found only 5 single base pair changes in *pagA* between 26 *B. anthracis* strains, using complete DNA sequence data for the gene. Further, LR REP-PCR analysis of 105 *B. anthracis* strains of diverse geographical origins allowed the strains to be classified into only five groups. A few explanations for the monomorphic nature of *B. anthracis* have been proposed. It may be that anthrax has a slow rate of evolution and divergence, although this is thought to be unlikely. Other possible explanations include a very recent origin for this species, giving it little time to evolve and diverge, or a population bottleneck that reduced its genetic diversity in the recent past.

So far, the best screening method for distinguishing *B. anthracis* strains has been MLVA. In one study, MLVA of 426 *B. anthracis* isolates using 8 VNTR loci identified 89 distinct genotypes that could be studied in terms of their genetic relatedness. MLVA was used for molecular subtyping of *B. anthracis* in the 2001 anthrax outbreak. All 135 isolates from the outbreak had identical MLVA characteristics. Rather than being useful for distinguishing this strain from others, MLVA characterization turned out to be useful for the confirmation that each case was caused by the same *B. anthracis* strain and for separating these results from environmental contamination. During this investigation, it became clear that MLVA was not sufficient to determine the origin of the attack strain. On the basis of MLVA analysis, the strain of *B. anthracis* isolated in the attacks appeared to be identical to the Ames strain that is used by many research labs, so this technique did not provide the resolution necessary for the genetic investigation.

As the *B. anthracis* genome sequence was nearing completion at this time, research turned to comparing the DNA sequence of the *B. anthracis* strain isolated from a patient who contracted anthrax in Florida with that of the Porton isolate of the Ames strain, which was used to generate the standard *B. anthracis* genome sequence. Even at this level of resolution, only four differences were found between the chromosomal sequences of the Florida and Porton isolates. As for plasmid sequences, the Porton isolate has been cured of its plasmids, so the pXO1 and pXO2 sequences of the attack isolate were compared with those of the Sterne (pXO1) and Pasteur (pXO2) strains. A total of 38 single nucleotide polymorphisms, 8 VNTRs, 3 insertion/deletion polymorphisms, and 2 inversions were identified. One of the inversions was found on pXO1 and was centered on the pathogenicity island. In fact, the Florida isolate contained a mixture of both orientations of this plasmid segment, confirming the fact that this DNA segment can invert, as had been suggested previously.

The polymorphisms identified in this sequence comparison were then used in an attempt to distinguish five additional Ames isolates that previously had been indistinguishable. When plasmid sequences were compared, one laboratory isolate and a strain isolated from an infected goat did have a small number of plasmid sequence differences that allowed them to be classified separately. The polymorphisms identified in this study also enabled researchers to readily distinguish two non-Ames *B. anthracis* strains from the Ames strains. However, the remaining three Ames lab isolates and the Florida strain could not be distinguished from each other, on the basis of either the chromosomal or plasmid sequences.

Owing to the monomorphic nature of the *B. anthracis* genetic composition, direct sequence comparisons between isolates are the most effective method for distinguishing related strains. Even with this complete sequence comparison, it is not possible to distinguish between all isolates, as indicated by the difficulty in distinguishing between various isolates of the Ames strain.

4 Regulation of Virulence

As mentioned above, the major virulence factors for *B. anthracis* are a poly-D-glutamic acid capsule and the anthrax toxin. Synthesis of the capsule requires four genes: *capA, capB, capC*, and *dep (capD)*. The toxin, composed of protective antigen, edema factor, and lethal factor, is encoded by *pagA, cya*, and *lef* respectively. The genes encoding these factors are expressed in a regulated fashion, through the action of two major regulators, AtxA and AcpA, but additional regulatory factors are also involved. A figure summarizing the virulence regulation pathways in *B. anthracis,* as we currently understand them, is shown in Fig. 6.

4.1 AtxA

The toxin genes and *atxA* are expressed by vegetative cells shortly after spore germination in cultured macrophages. Expression of *atxA* at this time is important because it is essential for the release of the bacteria from macrophages. The *atxA* gene is located on pXO1 between the *cya* and *pagA* genes. In $atxA^+$ strains, the toxin genes are coexpressed, and this expression is enhanced by elevated CO_2 levels and temperature, with induction at

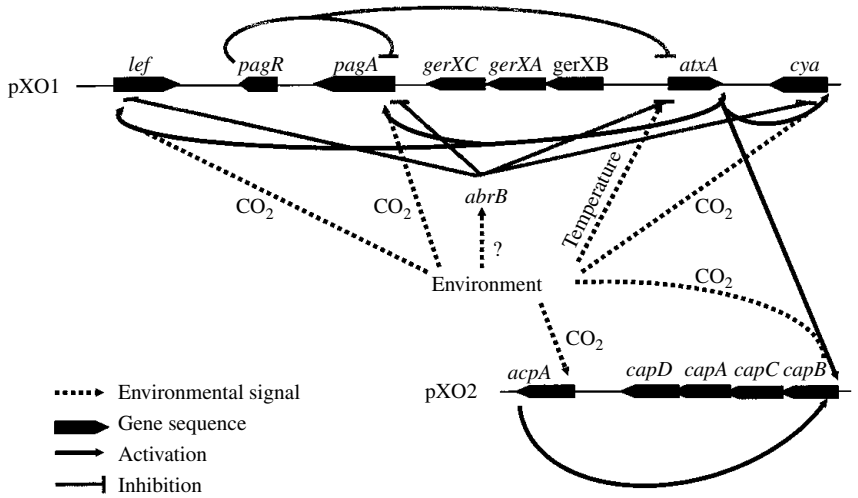

Fig. 6 Regulation of plasmid-encoded virulence gene expression. This figure is an overview of regulatory pathways known to be involved in *B. anthracis* virulence gene expression. Additional factors involved in the control of virulence gene expression will certainly be identified in the future. Although environmental signals are known to be crucial for regulation of virulence gene expression, the mechanism for this signaling is not known, nor have all of the factors involved in environmental sensing probably been identified.

5% CO_2 and 37 °C. *AtxA*$^-$ strains show significantly reduced production of all three toxin proteins in culture and are avirulent in a mouse model.

AtxA is an activator of toxin synthesis that acts at the transcriptional level. Although *pagA*, *lef*, and *cya* are transcribed as part of an AtxA-dependent regulon, there are no obvious sequence similarities upstream of the virulence genes that would suggest an AtxA binding site, nor does the AtxA protein sequence suggest any characteristics of DNA-binding proteins, so the mechanism it uses to regulate transcription of these genes is not clear.

The temperature requirement for toxin synthesis is at the level of the *atxA* transcript, as steady state levels of *atxA* mRNA are significantly increased in cells grown at 37 °C compared to cells grown at 28 °C. Higher levels of AtxA do not directly translate into increased levels of toxin production, however. Strains that carry *atxA* on a multicopy plasmid have high levels of AtxA, but they do not produce more, and some strains even produce significantly less, protective antigen than do matched strains carrying *atxA* in a single copy on pXO1. Further, although CO_2-enhanced toxin expression is AtxA-dependent, CO_2 does not affect AtxA levels. Although altering AtxA levels does not directly lead to an alteration of toxin levels, it can have a regulatory effect. It has been reported that some *B. anthracis* strains carrying a multicopy plasmid encoding *atxA* produce toxin in a CO_2-independent fashion in contrast to the CO_2-dependence seen in the parental strain.

The toxin genes are not the only *B. anthracis* genes that are AtxA-regulated. The presence of pXO1 also increases capsule synthesis. AtxA appears to be necessary and sufficient for this stimulation, as indicated by enhanced transcription of a *capB-lacZ* fusion in an AtxA-dependent manner. To identify additional AtxA-dependent gene expression, Hoffmaster and Koehler used a *lacZ*-containing transposon as a marker for genes that were induced by CO_2 in an AtxA-dependent manner. In this scheme, *lacZ,* which is a gene whose expression can be easily monitored, will be placed randomly under the control of the regulatory sequences of the gene into which the tranposon inserts. *lacZ* expression will therefore mark genes that are expressed under the conditions of interest – in this case, the presence of CO_2 and AtxA. In this experiment, there were 10 independent transposon insertions with AtxA-dependent expression that did not map to the toxin genes. Two-dimensional electrophoresis of protein extracts from *atxA*+ versus *atxA*−cells also indicates that synthesis of nontoxin proteins is influenced by AtxA. Some of these AtxA-regulated genes may play a role in the growth of *B. anthracis*, because *atxA*-null mutations cause *B. anthracis* to grow poorly on certain minimal media, and in sporulation, because an *atxA*-null mutant sporulates more efficiently than the parent strain when grown in rich media. Finally, *atxA*, but not the toxin genes, is required for release of *B. anthracis* from macrophages, so an *atxA*-regulated gene is likely to be involved in this process.

4.2 PagR

One of the CO_2-enhanced, *atxA*-dependent loci on pXO1 is a repressor of the *pagA* operon that serves to limit *pagA* expression under conditions optimal for PA synthesis. It was named *pagR* for protective antigen repressor. *pagR* is located downstream of

pagA and is cotranscribed with that gene. Transcription from the *pagA* promoter results in a monocistronic transcript containing *pagA* alone, and in a bicistronic transcript that encodes both *pagA* and *pagR*. Expression of *pagR*, as with *pagA*, is *atxA*-dependent and CO_2-enhanced. PagR has sequence similarity to transcription regulators, and it has been found that the level of the *pagA* transcript, and PA protein, is higher in a *pagR* mutant than in its parent strain, indicating that PagR normally represses *pagA* expression. Interestingly, PagR also represses *atxA* expression; the *pagR* mutant strain produces approximately twofold more *atxA* mRNA than its parent strain. It is not believed that the effects of *pagR* on *pagA* expression occur through AtxA because AtxA levels are not limiting for *pagA* expression.

Before *pagR* was discovered, a mutant *B. anthracis* strain was found that expressed the toxin genes in the absence of CO_2. An unidentified virulence regulator was therefore proposed. This strain was postulated to have a mutation in a negative regulator of toxin gene expression, whose repressive effect is alleviated in the presence of CO_2, thereby allowing AtxA to stimulate toxin expression. CO_2 has the opposite effect on *pagR*-regulated toxin expression – it would be predicted to decrease toxin gene expression because it stimulates *pagR* expression. *pagR*, therefore, cannot be the sole CO_2-dependent regulator of toxin gene expression because CO_2 has the overall effect of increasing toxin gene expression, rather than limiting it. Does CO_2 turn off the proposed repressor while at the same time increasing repression by PagR so that toxin gene expression does not get out of control? Unfortunately, several things about the CO_2 regulatory system are unknown, including the effects of PagR on expression of *lef* and *cya*, the effect of CO_2 on toxin expression in a *pagR* mutant, and the identity of the gene mutated in the strain that produces toxin in the absence of CO_2. As such, more research needs to be done before the regulatory pathways that limit anthrax toxin synthesis are fully understood.

4.3 AbrB

Another regulator of toxin expression is *abrB*, an ortholog to *abrB* from *Bacillus subtilis*. The *B. subtilis* gene is a transition state regulator, meaning it mediates the transition of cells from one state to another, such as from quiescence to active growth. The *B. anthracis* ortholog is located on the chromosome and appears to work similarly. An *abrB* null mutant shows increased expression of toxin gene–lacZ reporter fusions, with the largest effect seen for *pagA::lacZ*. Slightly elevated expression of an *atxA::lacZ* reporter was also found in the *abrB* null mutant, although, in the reciprocal experiment, *abrB* expression was found to be independent of *atxA*. Thus, similar to *pagR*, *abrB* appears to be a negative regulator of toxin gene and *atxA* expression. As with *pagR*, however, the *abrB*-mediated regulation of toxin gene expression is not believed to occur solely through *abrB*'s effects on *atxA* expression because AtxA levels in cells are not limiting for toxin gene expression.

In *B. subtilis*, *abrB* is regulated by Spo0A. The situation is similar in *B. anthracis*. Normally, low levels of AbrB are found in early log phase. These levels increase to a maximum level in log phase then drop back down to a low level as the cells enter stationary phase. In contrast, AbrB in an *spo0A* mutant persists at high levels in stationary phase, suggesting that *abrB* expression is normally negatively

regulated by *spo0A*. In conjunction with these findings, the pattern of toxin gene expression is affected by *abrB*. In a parent strain, toxin expression increases gradually throughout log phase, reaching a maximum in late log phase. The derivative *abrB* mutant strain, on the other hand, shows a sharp increase in toxin gene expression in early log phase, and maximum expression is reached in mid-log phase before a decline in expression is seen in late log phase. Although it has not yet been tested, it is likely that signaling pathways containing AbrB play a role in environmental sensing in *B. anthracis*, as they do in *B. subtilis*.

4.4 AcpA

Another major virulence regulator in *B. anthracis* is AcpA, a protein with significant similarity to AtxA. AcpA is encoded by a gene on pXO2 and is a regulator of capsule production that works at a transcriptional level. Northern blots indicate that the genes for capsule production, *capA* to *capD*, are transcribed as one message and thus constitute an operon. Strains with mutations in *acpA* are significantly reduced in capsule production and in virulence. AcpA is involved in the bicarbonate-mediated regulation of capsule production. Unlike AtxA, whose production requires a temperature of 37 °C, *acpA* transcription is regulated by bicarbonate.

Green et al. reported that the requirement for CO_2 in capsule production increases in the absence of pXO1. And, as mentioned above, the presence of pXO1 increases capsule synthesis in an AtxA-dependent manner. This led Uchida et al. to speculate that AtxA may work with AcpA to induce capsule production. Indeed, they found that an *acpA*-null mutant is complemented, not only by *acpA* but also by *atxA* in a CO_2-dependent fashion. This regulation is at the level of transcription, and the same sequences upstream of *cap* are required for both AtxA- and AcpA-mediated activation of transcription. Reciprocal experiments suggest that AcpA cannot complement an *atxA* defective strain. No obvious similarities between the sequences upstream of *pagA* and *cap* have been identified, so an AtxA target sequence is yet to be identified.

4.5 Other Potential Virulence Factors

Homologs of virulence genes from closely related species have been identified in *B. anthracis*, but their roles in virulence have not been fully studied. These include extracellular proteases, hemolysins, enterotoxins, and phospholipases. In *B. cereus* and *B. thuringiensis*, the expression of some of these nonspecific virulence factors is regulated by PlcR, a pleiotropic activator. Strains of *B. cereus* and *B. thuringiensis* with *plcR* deletions have attenuated virulence in a mouse model, indicating that the proteins turned on by this regulator do, in fact, play a role in virulence. In contrast, wild-type, fully virulent *B. anthracis* has a nonsense mutation in *plcR* and encodes a truncated, nonfunctional protein. This mutation silences a regulon; if a functional *plcR* is expressed in *B. anthracis*, a number of genes are activated. The addition of a functional *plcR* does not, however, affect the virulence of the organism, but it does inhibit sporulation of *B. anthracis* in an *atxA*-dependent manner. A strain that carries a functional *plcR* but no functional *atxA* sporulates normally. It has been postulated, therefore, that, after the acquisition of pXO1, there may have been counterselection for the

plcR regulon in *B. anthracis* because it puts the bacteria at a selective disadvantage due to its effect on sporulation.

5 Regulation of Sporulation/Germination

Appropriate sporulation and germination responses are crucial for the survival of *B. anthracis*. Spores can survive for years and can withstand harsh environmental conditions. The spores must be able to sense and respond to the environment, such that germination occurs under the appropriate conditions. In the case of *B. anthracis*, spores must germinate once they are taken up by a host so that the bacteria can replicate and the disease can be established. A tricistronic operon on pXO1 is responsible for spore germination. The genes in this operon, *gerXB*, *gerXA*, and *gerXC*, are located between *pagA* and *atxA* on the plasmid. The *ger* genes have significant similarity to the germination genes found in other bacilli, such as the *gerB* operon of *B. subtilis* and the *gerI* operon of *B. cereus*. In culture, expression of this operon is barely detectable during exponential growth and increases rapidly during stationary phase so that maximal expression is seen 3 h after the initiation of sporulation. Expression is limited to the developing forespore. In macrophages, spores of a *gerX* null mutant do not germinate as readily as do wild-type spores, and this is also true in mice infected subcutaneously with the *gerX* null strain. In the animals, there is a significant delay in the onset of germination with the *gerX* mutant, and this is associated with a fivefold decrease in virulence. Once the gerX null spores have germinated, they are able to multiply and invade the host. It has been speculated that the rate of germination may affect the rate of the infection and that this may play a role in the reduced virulence of this strain.

The *gerX* operon is not the only regulator of sporulation and germination in *B. anthracis*; plasmidless strains of *B. anthracis* germinate and grow in animal models. Inosine and L-alanine are two of the major germinants that induce plasmidless strains to germinate. At physiological levels, these germinants work only in combination with other compounds. For alanine, an aromatic amino acid (either L-histidine, L-tyrosine, or L-tryptophan) is also required for germination, and this has been termed the *aromatic-enhanced alanine* response (AEA). For inosine, either a nonaromatic amino acid or an aromatic amino acid are required as cogerminants, and these exhibit different germination kinetics. These responses have been called AAID for amino acid – and inosine-dependent responses. A *gerX* homolog was found on the chromosome of *B. anthracis* and called *gerS*. Characterization of a *gerS* mutant indicated that it is involved in both the AAID and AEA germination responses. Analogous to the situation in even more well-characterized germination pathways in other bacilli, it has been proposed that *gerS* encodes an aromatic responsive element that works in conjunction with other sensors to detect germinants with multiple components. Homologs of *gerI* and *gerL* from the *B. cereus* germination operon have been identified in the *B. anthracis* genome, and they may be components of this pathway.

6 Conclusions

Great strides have been made recently in the development of methods for the

detection of *B. anthracis*. These methods will facilitate the investigation of anthrax outbreaks in the future. Although research yields ever-increasing knowledge of the molecular biology of *B. anthracis*, much more work remains to be done to achieve a full understanding of this organism's life cycle, how it evolved into such a deadly pathogen, and how its virulence is controlled. As has been outlined in this review, *B. anthracis* shows evidence of gene functions that are encoded by unknown genes and of genes that encode proteins of unknown function. Further research on *B. anthracis*, which should be facilitated by the completed genome sequence, will hopefully make it possible to connect additional genes with their functions and result in a deeper understanding of the life cycle and pathogenesis of *B. anthracis*.

Keywords

Antibody/Antigen
Antibodies are proteins known as *immunoglobulins* (Igs), which are produced by the immune system in response to the presence of a foreign substance. Antigens are molecules (usually proteins) on the surface of cells, viruses, fungi, bacteria, and some nonliving substances such as toxins, chemicals, drugs, and foreign particles, which are recognized and specifically bound by antibodies. The immune system recognizes immunogenic antigens (also known as *immunogens*), and produces antibodies that destroy or neutralize substances or organisms containing antigens.

Antibody-dependent Cellular Cytotoxicity (ADCC)
Cell-killing reaction in which the Fc receptor bearing killer cells recognizes target cells via specific antibodies.

Bacteriophage
Bacteriophages or phages are viruses that infect bacteria. Bacteriophage λ is a temperate phage, which can grow lytically lysing the bacteria and forming a clear plaque on a lawn of bacteria. Infection with filamentous phages such as M13 is not lethal and the host bacteria do not lyse. Instead, their rate of growth slows and they form turbid plaques on the bacterial lawn.

Complement
Group of serum proteins participating in the lysis of foreign cells and pathogens [a process known as *complement-dependent cytotoxicity* (CDC)]; they also play an important role in phagocytosis.

Constant Region
Portion of the antibody molecule exhibiting little variation and determining the isotype (class or subclass) of the antibody.

Fab
The Fab fragment is a monovalent antigen-binding fragment of an antibody that consists of one light chain and part of one heavy chain (the variable region and the first constant region domain). It can be obtained by digestion of intact antibody with papain or by genetic engineering techniques.

Fc
The Fc is a nonantigen binding fragment of an antibody that consists of the carboxy-terminal portion of both heavy chains. It can be obtained by papain digestion of an intact antibody. Two Fabs and one Fc fragment comprise a complete IgG antibody.

Fv/scFv
The Fv is a monovalent antigen-binding fragment of an antibody composed of the variable regions from the heavy and light chains. scFv fragments are composed of the

variable domains of heavy and light chains (V_L and V_H) joined by a synthetic flexible linker peptide. Thus, the scFv provides a fully functional antigen binding domain that is encoded in a single gene and expressed as a single polypeptide.

Hybridoma
Cell derived by a fusion between a normal cell, usually a lymphocyte, and a tumor cell, usually a myeloma cell.

Variable Region
Variable portion of the antibody molecule that is responsible for antigen binding.

Antibodies have long been appreciated for their exquisite specificity. With the development of the hybridoma technology, it was possible to produce rodent (mouse or rat) monoclonal antibodies that are the product of a single clone of antibody-producing cells and have only one antigen-binding specificity. Advances in genetic engineering and expression systems have been applied to overcome problems of immunogenicity of rodent-produced antibodies and to improve their ability to trigger human immune effector mechanisms. The production of chimeric, humanized, and totally human antibodies as well as antibodies with novel structures and functional properties has resulted in improved monoclonal antibodies. As a consequence, recombinant antibody-based therapies are now used to treat a variety of diverse conditions that include infectious diseases, inflammatory disorders, and cancer. This article summarizes and compares different strategies for developing recombinant antibodies and their derivatives.

1
Antibody Structure and Engineering

1.1
The Basic Structure of Antibodies

Antibodies are molecules with multiple properties that make them a critical component of the immune system. These properties include the ability to recognize a vast array of different molecules known as *antigens* and to interact with and activate the host effector systems.

The basic structure of all antibodies, also known as *immunoglobulins* (Igs), is a unit consisting of two identical light polypeptide chains and two identical heavy polypeptide chains linked together by disulfide bonds (Fig. 1). Heavy and light chains are encoded by separate genes and are organized into discrete globular domains separated by short peptide segments. The amino-terminus end of both heavy and light chains is the antigen binding site and consists of one domain characterized by sequence variability (variable region or V) in both the heavy and light chains, called the V_H and V_L regions respectively. The rest of the molecule has a relatively constant (C) structure. The constant region of the light chain is termed

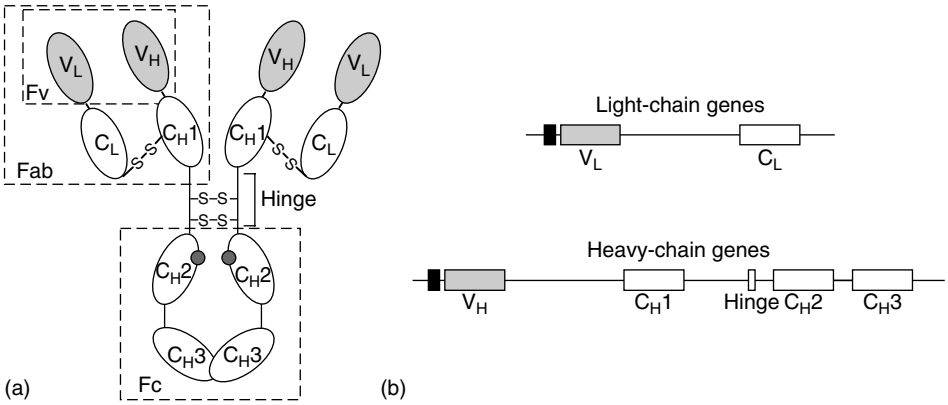

Fig. 1 (a) Diagram of an immunoglobulin G (IgG) molecule (the most abundant antibody in serum) and the active fragments that can be derived from it. The antibody molecule is divided into discrete functional domains: two domains constitute the light chain (V_L and C_L), while four domains make up the heavy chain (V_H, C_H1, C_H2, and C_H3). The variable region domains make the antibody binding site and are designated as the Fv region. The effector functions of the antibody are properties of the constant region domains. The carbohydrate units (black circles) present within the C_H2 domains contribute to the functional properties of the antibody. The hinge region provides flexibility to the antibody molecule, facilitating antigen binding and some effector functions. The enzyme papain cleaves the antibody into two Fab fragments containing the antigen binding sites and an Fc fragment responsible for the effector functions. (b) Genes that encode the heavy and light chains. In the genes, each domain is encoded by a discrete exon (indicated by boxes) separated by intervening sequences (introns) indicated by the line; the intervening sequences are present in the primary transcript but are removed from the mature mRNA by splicing. Both heavy and light chains contain hydrophobic leader sequences (indicated by the black exon) necessary for their secretion. This leader sequence is present in the newly synthesized heavy and light chains but is cleaved from them after they enter the endoplasmic reticulum and, therefore, is not present in the mature chains.

the C_L region. The constant region of the heavy chain is further divided into three structural domains stabilized by intrachain disulfide bonds: C_H1, C_H2, C_H3 (Fig. 1). The C_H3 domain of the heavy chain represents its carboxy-terminus. The domain structure of the antibodies is very important for genetic engineering because it facilitates protein engineering, allowing the exchange between molecules of functional domains carrying antigen-binding activities (Fabs or Fvs) or effector functions (Fc).

The hinge region, a segment of heavy chain between the C_H1 and C_H2 domains, provides flexibility in the molecule. Papain digestion of IgG yields two Fab fragments and one Fc fragment. The Fab region binds antigen, while the Fc region mediates effector functions such as complement activation, antibody-dependent cellular cytotoxicity (ADCC), and placental transmission. All antibodies are glycoproteins, and the carbohydrate present in the constant region has been shown to be essential for many of its effector functions.

1.2 Classes and Subclasses of Antibodies

The constant region of the heavy chain determines the class or isotype of the

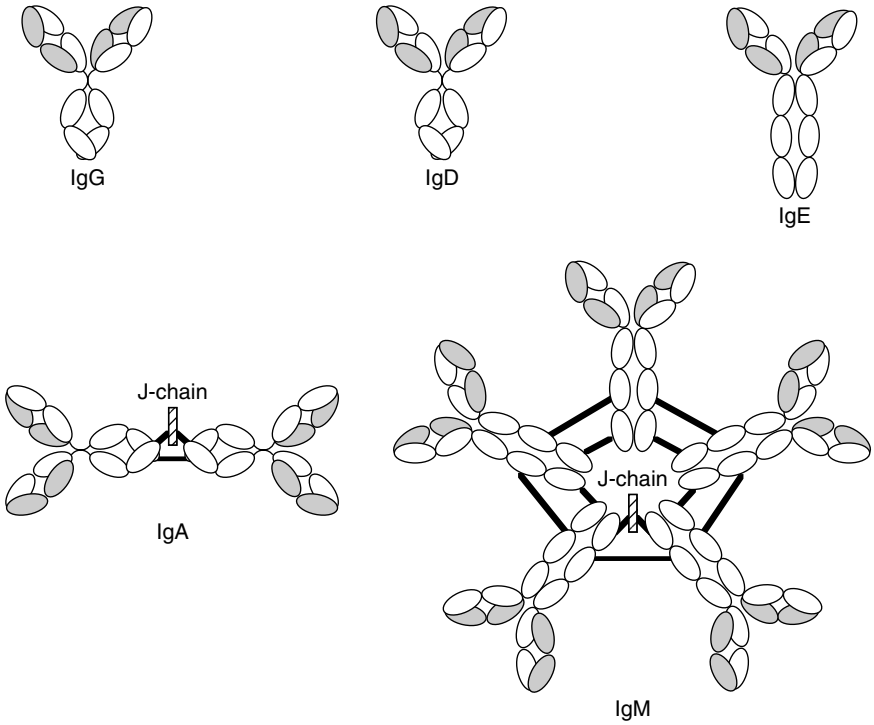

Fig. 2 The five classes of antibodies: IgG, IgD, and IgE are monomeric antibodies; IgA and IgM are polymeric antibodies.

antibody. Figure 2 shows the five different classes of antibodies, which differ in the constant region of their respective heavy chains. The different heavy-chain isotypes that define these classes of antibodies are designated by lower-case Greek letters: γ for IgG, δ for IgD, ε for IgE, α for IgA, and μ for IgM. IgM and IgE heavy chains contain an extra C_H domain (C_H4) and lack the hinge region found in IgG, IgD, and IgA. However, the absence of a hinge region does not imply that IgM and IgE lack flexibility; electron micrographs of IgM molecules binding to ligands have shown that the Fab arms can bend, relative to the Fc fragment. There are also two different light-chain isotypes, which are designated by the lower-case Greek letters κ and λ. Light chains of both isotypes are found associated with all the heavy-chain isotypes.

In humans, there is only one class of IgD, IgE, and IgM with monomeric structures having a molecular weight (MW) of around 190 kDa. However, human IgA antibodies can be further subdivided in two subclasses (IgA1 and IgA2) with a molecular weight of around 160 kDa for each monomer, and human IgG antibodies can be subdivided into four subclasses: IgG1, IgG2, IgG4 (all three with a molecular weight of around 150 kDa) and IgG3 with a molecular weight of around 165 kDa. The higher molecular weight exhibited by human IgG3 is due to the presence of an extended hinge region, which provides extraordinary flexibility. In fact, IgG3 is the most flexible human IgG.

Although all antibody molecules are constructed from the basic unit of two heavy and two light chains (H_2L_2), both IgA and IgM form polymers (Fig. 2). IgA forms a dimeric structure in which two H_2L_2 units are joined by a J-chain [$(H_2L_2)_2J$], and IgM forms either a pentameric structure with five H_2L_2 units joined by a J-chain [$(H_2L_2)_5J$] or a hexameric structure [$(H_2L_2)_6$], which does not have the J-chain (not shown). IgM and IgA heavy-chain constant regions contain a ''tailpiece'' of 18 amino acids that contains a cysteine residue essential for polymerization. The J-chain is a 15 kDa polypeptide produced by B-lymphocytes and plasma cells (the same cells that produce the antibodies) that promotes polymerization by linking to the cysteine of the tailpiece (Fig. 2). Differences in the isotype of the heavy chain determine the number of carbohydrate units and the ability to engage in various effector functions such as complement activation, ADCC, and placental transmission. Differences in the isotype of the light chain do not appear to significantly influence the structure or the effector functions of the antibody molecule.

2
From Mouse to Human Antibodies

2.1
Murine Monoclonal Antibodies

During the normal immune response, a wide variety of antibodies is produced. These antibodies, known as *polyclonal antibodies* (i.e. they are the product of many different antibody-producing cells), include antibodies with different variable regions as well as antibodies with the same variable regions associated with different constant regions. Rarely do different individuals mount an identical immune response. This heterogeneity in the immune response plus ethical and safety concerns has made it difficult to use polyclonal antibodies for many applications.

A significant breakthrough was made when it became possible to produce stable cell lines that synthesize a single homogeneous antibody (Fig. 3). By fusing a normal B-cell from the splenocytes of an immunized animal (initially a mouse or a rat) with a myeloma cell, it is possible to generate a ''hybridoma,'' which possesses the immortality of the myeloma cell and secretes the antibody characteristic of the normal B-cell. Antibodies produced by hybridomas are monoclonal (i.e. they are the product of a single antibody-producing cell) and therefore have a single variable region associated with only one constant region. The immortality of the hybridoma ensures the continued availability of a well-characterized antibody. Once a hybridoma cell line is developed, it can be grown *in vitro* or *in vivo* for large-scale production of the monoclonal antibody, or it can be used to clone the variable regions of the monoclonal antibody for genetic engineering purposes.

Owing to their high affinity and exquisite specificity, murine monoclonal antibodies seemed to be the ideal ''magic bullets'' for diagnosis or therapy of multiple diseases including cancer. However, the progression of ''magic bullets'' from dream to reality has been slow because mouse (murine) monoclonal antibodies are not the ideal agents to be administered into a human. Murine monoclonal antibodies compared to human antibodies require more frequent dosing to maintain a therapeutic level of monoclonal antibodies because of a shorter circulating half-life in humans than human antibodies. In addition, the

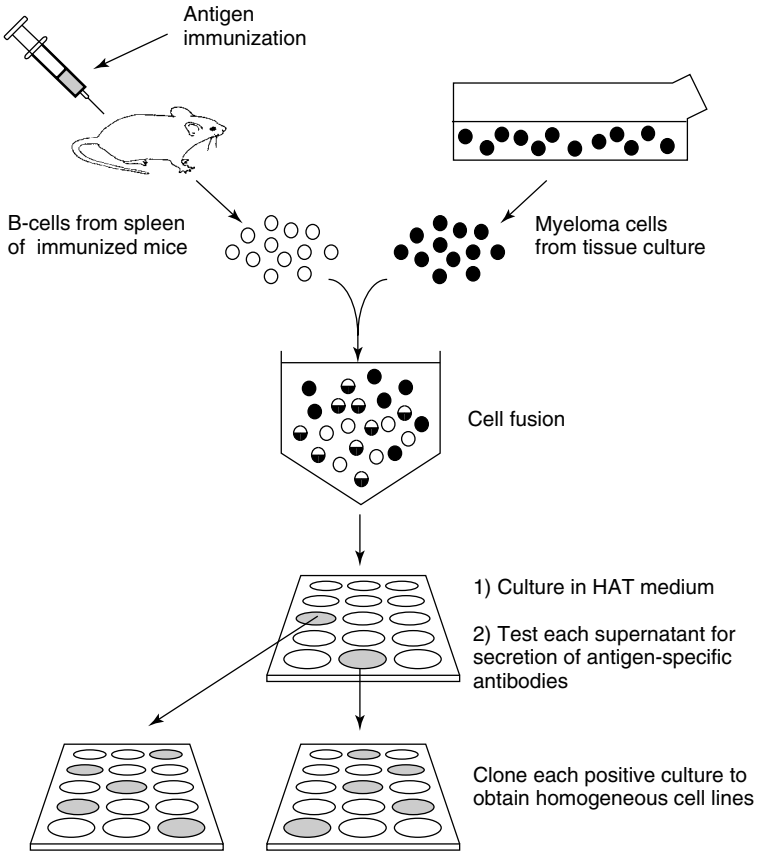

Fig. 3 Production of monoclonal antibodies. Mice are immunized with the antigen of interest and spleen cells are isolated and then fused with myeloma cells. HAT (hypoxanthine, aminopterin, and thymidine) medium is used to separate unfused myeloma cells from fused hybridoma cells. It takes advantage of the fact that normal mammalian cells can synthesize nucleotides by both a *de novo* and a salvage pathway, while the myeloma cells used have a defect in the salvage pathway. When the *de novo* pathway is blocked by aminopterin, cells must then utilize the enzymes of the salvage pathway. Thus, in the presence of aminopterin, unfused myeloma cells will die. Normal spleen cells do not grow. Only cells that have acquired the enzymes of the salvage pathway from the normal cells and the capacity for continuous growth from the myeloma cell will survive. Supernatants of hybridomas are screened for the presence of the antibody with the desired specificity, and positive cell cultures are subcloned to obtain a homogeneous cell line.

human immune system recognizes the mouse protein as foreign, generating a human antimouse antibody (HAMA) response, which results in an even more rapid clearance of the murine antibody (rendering the therapeutic useless) and, in some cases, in a severe allergic reaction. Moreover, murine constant regions can be ineffective in interacting with the human immune effector system. These

problems would be overcome by producing human monoclonal antibodies using human B-cells from immunized human donors. However, human monoclonal antibodies are difficult to produce using the hybridoma technology originally designed for the production of murine antibodies: the cell lines are unstable and frequently produce antibodies of the IgM isotype, which have low affinity for the antigen and are difficult to purify and handle. In addition, there are ethical and safety problems in obtaining humans immunized with certain antigens.

2.2 Chimeric Antibodies

To overcome the problems associated with the administration of murine monoclonal antibodies to humans, protein engineering has been used to convert murine monoclonal antibodies to mouse/human chimeric antibodies by genetically fusing the mouse variable regions to the human constant regions (Fig. 4), a procedure that is facilitated by the structure of antibodies.

Initially, variable region genes were obtained from genomic or cDNA libraries produced using DNA or mRNA from antibody-producing cells. More recently, cloning of genes encoding for the antibody variable region has been greatly facilitated by polymerase chain reaction (PCR)-based procedures. The variable region consists of hypervariable complementarity determining regions CDRs that are responsible for antibody specificity supported by relatively conserved framework regions. A limited number of different hydrophobic leader sequences are also found associated with the different variable regions. Therefore, it is possible to design sets of oligonucleotide primers on the basis of either the framework or the leader regions that will bind to virtually all mouse variable regions. A limited number of primers are required for all constant regions. Using upstream consensus primers for framework or leader regions in light- and heavy-chain variable regions and downstream primers for the constant regions, PCR can be used to amplify cDNAs generated by reverse-transcription (RT-PCR) directly from hybridoma mRNA.

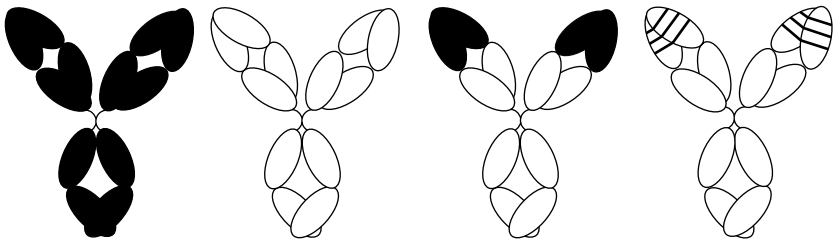

Fig. 4 Schematic representation of a murine monoclonal antibody, a human monoclonal antibody, a mouse–human chimeric antibody, and a CDR-grafted or humanized antibody. Chimeric antibodies have murine derived variable regions and binding specificities joined to human constant regions with their corresponding effector functions. Humanized antibodies are composed mostly of human sequences except for the areas in contact with the antigen (CDR regions), which are derived from mouse sequences.

This product is cloned and sequenced, and then used for the construction of chimeric antibodies or for further genetic modifications, as described below.

For the most part, chimeric antibodies retain their target specificity and show reduced HAMA responses. An example of a successful mouse–human chimeric antibody approved for clinical use is Rituximab (Rituxan/Mabthera), which targets the CD20 antigen and is now widely used to treat non-Hodgkin's lymphoma.

2.3 Humanized Antibodies

Although mouse–human chimeric antibodies are less immunogenic than mouse antibodies, in some cases they can still elicit a significant human antichimeric antibody (HACA) response. One approach to overcome this problem is to further manipulate the antibody variable region encoding for the antigen binding site resulting in humanized antibodies (Fig. 4). Each variable domain consists of a β-barrel with seven antiparallel β-strands connected by loops. Among the loops are the CDR regions. It is feasible to move the CDRs and their associated specificity from one scaffolding β-barrel to another, thereby creating ''CDR-grafted'' or ''humanized'' antibodies. However, it is rarely sufficient to move only the CDRs from a murine antibody onto a completely human framework because the resulting antibody frequently has reduced or no binding activity. In these cases, additional mouse residues near the CDRs are incorporated until binding is restored.

An example of a successful humanized monoclonal antibody that has been approved for clinical use is Trastuzumab (Herceptin), which has demonstrated significant antitumor activity in patients affected with breast cancer overexpressing the tumor-associated antigen HER2/*neu*.

2.4 Human Monoclonal Antibodies in Mice

Recently, mice have been produced that make antigen-specific antibodies that are totally human. To accomplish this goal, transgenic mice carrying portions of the human IgH and Igκ loci [in germ line configuration using megabase-sized YACs (yeast artificial chromosome)] were obtained that included the majority of the variable region repertoire, the genes for Cμ, Cδ and Cγ1, Cγ2, or Cγ4, as well as the *cis* elements required for their function. The IgH and Igκ transgenic was then bred into a genetic background deficient in the production of murine immunoglobulin. Therefore, the resulting mouse model, named *XenoMouse*, has elements of the human heavy- and light-chain loci in a murine context in which endogenous mouse heavy and light chains were disrupted.

The large and complex human variable region repertoire encoded on the immunoglobulin transgenes in XenoMouse strains support the development of large peripheral B-cell compartments and the generation of a diverse primary immune repertoire similar to that of adult humans. The human genes are compatible with mouse enzymes mediating class switching from IgM to IgG as well as somatic hypermutation and affinity maturation. Importantly, the immune system of the XenoMouse recognizes human antigens as foreign, with a concomitant strong human humoral immune response. The use of XenoMouse mice in conjunction with well-established hybridoma procedures (see Fig. 3) reproducibly results in human IgG monoclonal antibodies with

high affinity for human antigens and suitable for repeated administration to humans. To date, these engineered mice can produce only some of the human isotypes, but further genetic modification of these mice promises to expand their potential.

3 *In Vitro* Antibody Production by Phage Libraries

The production of monoclonal antibodies frequently requires several injections of antigen, which can take weeks to months. Hybridoma construction and screening require additional time. In addition, the immune response is often biased toward certain ''immunodominant'' epitopes of the antigen, making it difficult or impossible to produce monoclonal antibodies with the specificity desired for a particular use. Moreover, the production of antibodies against antigens conserved among species may be difficult or impossible. Phage display, a technology that allows the expression of immunoglobulin genes in bacteriophages (viruses that infect bacteria) without the need for developing hybridomas, provides an alternative approach that overcomes many of these problems.

In phage display, the heavy and light V-gene obtained from the spleen of an immunized mouse or from the peripheral blood of a naive or immunized donor are expressed as Fab or single-chain Fv (scFv) on the surface of filamentous phages (f1, M13, and fd). Phage libraries can be generated using variable antibody gene repertoires from any species including humans, or even synthetic sequences. Figure 5 shows the development of scFv libraries using a human donor.

Both scFv and Fab fragments can be expressed on the surface of filamentous bacteriophages (f1, M13, and fd) as either single or multiple copies of the antibody of interest depending on the phage protein used for fusion. Expression of multiple copies facilitates the identification and isolation of low-affinity antibodies. When functional antibody V domains are displayed on the surface of filamentous phages, the resulting phages bind specifically to antigen, and rare phages can be isolated on the basis of their ability to bind antigen. Multiple rounds of enrichment consisting of binding to immobilized antigen, expanding the bound phage, and further enriching by again binding to immobilized antigen can yield specific phages even if the desired specificity was present on less than 1 in 10^6 of the original phages in the library. The selected variable regions will generally have affinities similar to monoclonal antibodies and can be expressed as antibody fragments in the bacterium *Escherichia coli* or they can be used to produce complete antibodies and can be expressed in mammalian hosts. In addition, specific variable regions can be mutagenized and phages that express variable regions with increased affinity can be selected. The bacteriophage expression systems are designed to allow the genes encoding for heavy and light chains to undergo random combinations, which are tested for their ability to bind the desired antigen.

The decision of whether to produce scFv or Fab libraries depends partly on the intended use. The single gene format of the scFv is an advantage for the construction of fusion proteins such as ''immunotoxins'' (antibodies or antibody fragments fused to a toxin) or for targeted gene therapy approaches where the *scFv* gene is fused to a viral envelope protein gene. The use of scFv also appears to

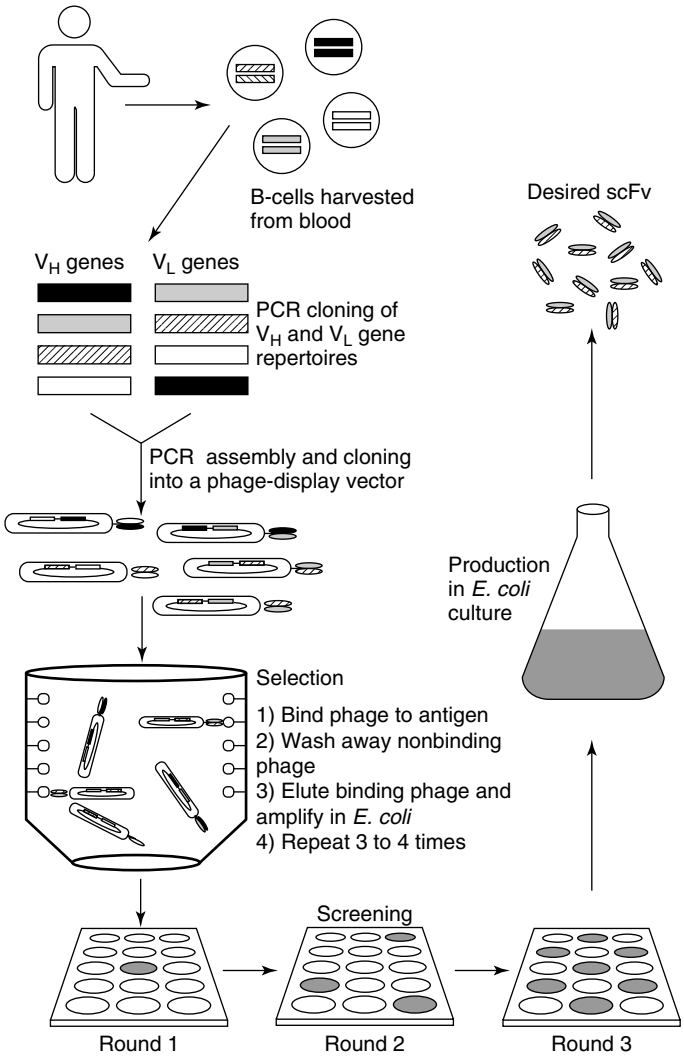

Fig. 5 *In vitro* human antibody production using phage libraries (phage-display technology). Peripheral blood mononuclear cells are harvested from a nonimmunized or immunized human donor, and the heavy- and light-chain V-gene regions (V_L and V_H) are amplified by PCR and assembled as a single-chain Fv region (scFv). Note that the original heavy- and light-chain pairings become scrambled during scFv assembly. The scFv genes are cloned into filamentous bacteriophages, where the encoded scFvs are displayed in a functional form on the phage surface. Multiple rounds of selection with a solid-phase antigen allow the isolation of even rare phages from the original library. The selected scFv can be expressed in *E. coli* (The illustration was adapted from Powers D.B. and Marks J.D. Monovalent Phage Display of Fab and scFv fusions. In *Antibody fusion proteins*. John Wiley & Son, Inc., New York, 1999).

be a better option for ''intracellular immunization,'' a procedure in which the gene encoding the antibody binding site is delivered intracellularly to achieve phenotypic knockout. However, the use of Fab fragments offers the advantage that heavy- and light-chain libraries can be produced independently and reassorted. The use of two vectors also facilitates the construction of hierarchical libraries in which a fixed heavy or light chain is paired with a library of partners. In theory, Fab libraries may be preferred where the final product will be a complete antibody, since, in some instances, removal of the scFv linker might alter the antigen-binding properties. However, scFvs have been successfully converted into complete antibodies.

Phage display has proved to be very effective in generating a variety of antibodies that are difficult to obtain using the hybridoma technology. For preexisting mouse monoclonal antibodies, phage display can be used to obtain antibodies that are entirely human in sequence, but which bind to the same part of the antigen (epitope) as the mouse monoclonal antibodies. Antibodies to targets previously inaccessible using immunization approaches (for example, self-antigens, ubiquitous compounds, or toxic compounds) have been isolated by selection of phage on antigen *in vitro*. Building on the concept of phage display, alternative display strategies such as ribosome display and cell-surface display have been recently developed.

4
Further Genetic Modifications of Antibodies

4.1
Engineering Antibody Fragments: Monovalent, Bivalent, and Multivalent scFvs

As explained in Sect. 3, scFv fragments consist of the variable domains of heavy and light chains (V_L and V_H) genetically fused by a flexile linker peptide. scFvs are much smaller than intact antibodies (Fig. 6) (25–27 kDa vs around 150 kDa for intact IgG), yet can retain the specificity and the affinity of the parental molecule. The small size of scFvs is a tremendous

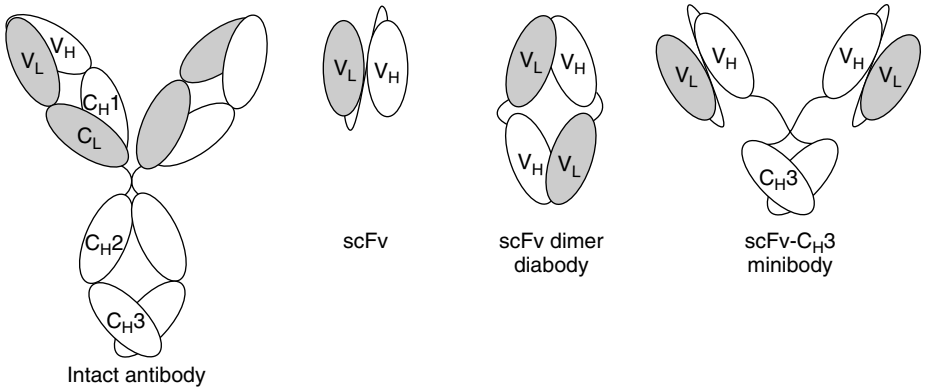

Fig. 6 Schematic representation showing the relative size and domain relationships between intact IgG (around 150 kDa) and engineered single-chain Fv (scFv, 25–27 kDa), scFv dimer or diabody (55 kDa), and minibody (scFv-C_H3, 80 kDa) fragments.

advantage in certain applications such as tumor targeting for detection and/or therapeutic purposes. In fact, scFv fragments display a combination of rapid, high-level tumor targeting with concomitant clearance from normal tissues and circulation that have made radiolabeled scFvs important tools for detection and treatment of cancer metastasis in both preclinical models and patients. An example of a successful scFv in the clinic is MFE-23. This scFv is specific for carcinoembryonic antigen (CEA), a glycoprotein that is highly expressed in colorectal adenocarcinomas. MFE-23, expressed in bacteria, has been used in two clinical trials: a gamma camera imaging trial using ^{123}I-MFE-23 and a radioimmunoguided surgery trial using ^{125}I-MFE-23, in which tumor deposits are detected by a handheld probe during surgery. Both trials showed that MFE-23 is safe and effective in localizing tumor deposits in patients with cancer.

Despite their successful use in some tumor-targeting studies, a significant limitation of using scFvs for targeting *in vivo* is their monovalent binding to antigen. Intact antibodies have significant avidity as a result of the presence of two antigen binding sites. To address this problem, antibody engineers have used the monomeric scFv as a building block for larger engineered fragments. One approach consists of producing dimers of scFv by incorporating a carboxy-terminal cysteine residue so that a disulfide bridge forms, yielding $(scFv)_2$ fragments. Alternately, the single-chain concept has been extended by using an additional linker peptide to join the two scFv molecules in tandem. Another approach for the production of scFv dimers results from the observation that the use of a very short linker peptide to connect the antibody variable regions caused the formation of ''cross-paired'' dimers, in which the V_L of one molecule associates with the V_H of a second and the V_L of the second molecule associates with the V_H of the first (Fig. 6). These noncovalent dimers, also known as *diabodies*, are capable of bivalent binding to antigen. scFv dimers and diabodies have a molecular weight similar to that of the antibody Fab fragments (55–60 kDa) but contain two antigen binding sites. Diabodies show significant improvement in tumor targeting compared to monovalent scFv. scFv fragments can also be fused to an immunoglobulin C_H3 domain, resulting in a self-assembling bivalent ''minibody'' (Fig. 6).

To further increase the avidity of antibody fragments, several laboratories have generated fragments with an increased valence. One strategy to develop fragments with increased valence has been to extend the diabody approach by decreasing the length of the interdomain linker peptide, which may result in the formation of tribodies and tetrabodies. It is also possible to obtain larger bivalent or multivalent fragments by fusing scFvs to protein domains normally involved in protein association such as helix bundles or leucine zippers. An alternative approach for producing multivalent fragments has been the fusion of scFvs to the bacterial protein streptavidin. Since streptavidin is a tetramer composed of four noncovalently linked monomers, four scFvs assemble to form a tetrameric structure with four antigen binding sites. A practical example of this technology was the development of Rh-specific scFv fused to streptavidin. This fusion protein named scFv::strep was able to directly agglutinate antigen-positive red blood cells (a reaction that is impossible to achieve by using antigen-specific monomeric scFv or IgG), suggesting the potential use of scFv::strep as a blood-typing reagent.

4.2 Bispecific Antibodies

In contrast to normal antibodies, which are monospecific, bispecific antibodies contain binding sites with two different specificities. Antibodies with two different specificities have been prepared by chemical modification to combine univalent fragments of different pepsin-treated antibodies, by fusing two hybridomas secreting antibodies of different specificities yielding a quadroma and by joining two different single-chain antibodies (scFvs). However, chemical modification of antibodies is inefficient and can lead to side reactions that damage the combining site. In a quadroma, it is difficult to separate the desired bispecific antibodies from the mixed population of heavy and light chains produced by the two hybridomas, and scFvs lacking constant regions also lack the antibody effector functions, which may be critical in certain applications. To address these problems, novel bispecific antibodies have been produced in which an scFv of one specificity has been genetically fused after the hinge (hinge-scFv) or at the carboxy-terminus (C_H3-scFv) of an antibody with a different specificity. Both fusion proteins were expressed by gene transfection in the context of a murine variable region. Transfectomas secreted a homogeneous population of the recombinant antibody with the two different specificities, one at the amino-terminus (anti-dextran) and the other at the carboxy-terminus (anti-dansyl). The C_H3-scFv antibody, which maintains the constant region of human IgG3, has some of the associated effector functions such as long half-life and Fc receptor binding. As expected, hinge-scFv antibody, which lacks the C_H2 and C_H3 domains, has no known effector functions.

Bispecific antibodies provide potential tools for use in immunotherapy. They take advantage of the great specificity of variable regions for their antigens and can be envisioned as transporters of therapeutic drugs or molecules or even immune effector cells to the specific targets identified by one of their binding sites. In fact, bispecific antibodies have been shown to be beneficial in the recruitment of immune cells for the treatment of cancer. Depending on the effector/target interaction, bispecific antibodies enhance cytotoxicity and phagocytosis. Several of these antibodies are currently undergoing evaluation in phase I and II clinical trials. Among the most extensively studied bispecific antibodies are 2B1 and MDX-210. 2B1 produced from a hybrid hybridoma is specific for the tumor-associated antigens HER2/*neu* and FcγRIII (CD16, the Fc gamma receptor expressed by key cytotoxic effector cells such as natural killer cells, neutrophils, and activated mononuclear phagocytes), while MDX-210 is a chemically conjugated hetero F(ab)′2 fragment specific for HER2/*neu* and FcγRI (CD64, the Fc gamma receptor expressed by key cytotoxic effector cells such as monocytes, macrophages, and IFN-γ–activated granulocytes). Both antibodies showed therapeutic promise in late-stage cancer patients whose tumor was refractory to conventional therapy. Since conventionally prepared bispecific antibodies have already shown promise in clinical trials and results from preclinical studies of recombinant bispecific antibodies are encouraging, in the future recombinant bispecific antibodies will undoubtedly be used in multiple clinical trials.

4.3
Polymers of Monomeric Antibodies

Although IgM is a naturally occurring polymeric antibody (see Fig. 2), for several applications it is desirable to have other classes of antibodies in an IgM-like (polymeric) structure. For example, IgM does not bind the Fc receptors on phagocyte cells, whereas IgG effectively triggers effector functions mediated through gamma-specific Fc receptors. In addition, since in IgG both heavy and light variable regions are usually somatically mutated (because of isotype switching to IgG), it is expected that polymeric IgG may be of higher intrinsic and functional affinity than the currently available IgM, resulting in more sensitivity and/or specificity. In addition, many methods such as protein-A binding are available that facilitate the isolation of IgG.

Vectors have been developed for the construction and expression of human polymeric IgG. It was observed that the 18–amino acid carboxyl-terminal tailpiece from human μ heavy chain is sufficient for polymer assembly. This finding was exploited to produce IgM-like polymers of IgG by fusing the 18–amino acid carboxyl-terminal tailpiece from human μ to the carboxyl-terminal of γ constant regions (Fig. 7). Using this technique, IgM-like polymers of IgG1, IgG2, IgG3, and IgG4 have been produced. IgGs obtained by this approach possess up to 6 Fcs and 12 antigen-combining sites, greatly increasing the avidity of their interactions with other molecules. These polymeric antibodies possess the Fcγ receptor–binding properties of IgG. Not surprisingly, the complement activity of normally active IgG1 and IgG3 and somewhat less-active IgG2 antibodies is dramatically enhanced upon polymerization. An unexpected result is that IgG4, normally devoid of complement activity, when polymerized in the same fashion directs complement-mediated lysis of target cells almost as effectively as the other polymers. These experiments demonstrate that polymerization of monomeric antibodies such as IgG is an effective approach to obtain antibodies with broader and more powerful effector functions than their wild-type counterparts.

An alternative strategy to make polymers of IgG is to genetically fuse chicken

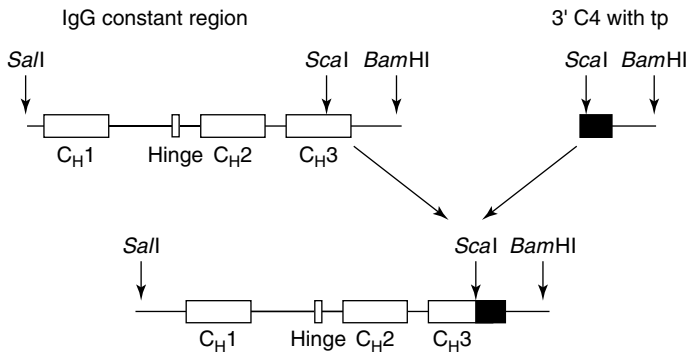

Fig. 7 Strategy for the construction of polymeric IgG. Using appropriate restriction sites, the μ tailpiece (μtp) of human IgM is genetically fused to the end of the heavy chain of human IgG.

avidin to the carboxy-terminus of the heavy chain of IgG. This approach is similar to that described in Sect. 4.1 (production of tetramers of scFv by fusing it with streptavidin) based on the fact that both streptavidin and avidin are tetramers of four noncovalently linked monomers. Since each antibody-avidin protein contains two molecules of avidin (one genetically fused at the carboxy-terminus of each heavy chain), two independent antibody fusion proteins bind to each other through their respective avidins forming a dimeric structure. One example of this approach is a recently developed human IgG3-avidin fusion protein specific for the transferrin receptor (TfR). The anti-TfR IgG3-avidin was able to function as a universal vector to deliver different biotinylated compounds into cancer cells overexpressing the TfR. Furthermore, it was unexpectedly discovered that anti-TfR IgG3-avidin, but not a recombinant anti-TfR IgG3 or a nonspecific IgG3-avidin, possesses a strong antiproliferative/proapoptotic activity against hematopoietic malignant cell lines. Studies confirmed that anti-TfR IgG3-avidin exists as a dimer, suggesting that cross-linking of the surface transferrin receptor may be responsible for the cytotoxic activity. These findings demonstrate that it is possible to transform an antibody specific for a growth factor receptor that does not exhibit inhibitory activity into a novel drug with significant intrinsic cytotoxic activity against selected cells by fusing it with avidin. The antitumor activity may be enhanced by delivering biotinylated therapeutics into cancer cells. Further development of this technology may lead to effective therapeutics for *in vivo* eradication of hematological malignancies and *ex vivo* purging of cancer cells in autologous transplantation.

4.4 Antibody Fusion Proteins

Fusion proteins with nonantibody molecules fused to antibodies can be produced using different approaches. Antibody fusion proteins that contain an intact antigen binding site should retain the ability to bind antigen, while the attached nonantibody partner should be able to exert its function. Such molecules, which have been called *immunoligands*, can be produced in several different ways (Fig. 8 a–f). When the nonantibody partner is fused to the end of the C_H3 domain (C_H3-ligand) (Fig. 8a), the antibody-combining specificity can be used to deliver an associated biological activity as well as antibody-related effector functions. An example is the anti-TfR IgG3-avidin fusion protein described in Sect. 4.3. Other examples are antibodies targeting cancer cells fused with interleukin-2 and GM-CSF. The goal of this approach to cancer therapy is to concentrate the cytokine in the tumor microenvironment and, by so doing, enhance the tumoricidal effect of the antibody and/or the host immune response against the tumor, while limiting severe toxic side effects associated with a high dose of cytokine administration. Such antibody–cytokine fusion proteins have shown significant antitumor activity in mice bearing tumors, leading to clinical trials. Immunoligands with the nonantibody partner fused immediately after the hinge (H-ligand) (Fig. 8b) or to the C_H1 domain (C_H1-ligand) (Fig. 8c) may be useful when the antibody-related effector functions are unnecessary or harmful. In addition, for many applications such as tumor targeting, the small size of the H-ligand and C_H1-ligand may be an advantage over the larger C_H3-ligand.

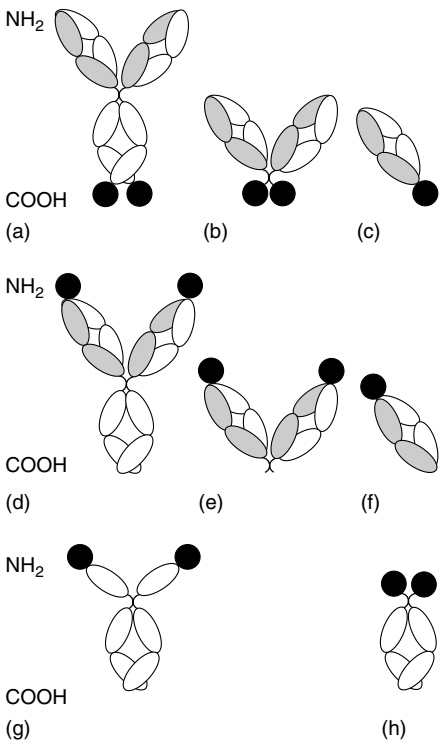

Fig. 8 Schematic representation of antibody fusion proteins. (a) to (c) represent different antibody fusion proteins in which the nonantibody partner was fused at the carboxy-terminus after the C_H3 domain (a), immediately after the hinge (b), or after the C_H1 domain (c). (d) to (f) represent antibody fusion proteins in which the nonantibody partner has been joined to the amino-terminus of the full-length heavy chain (d) or the truncated heavy chain (e and f). (g) and (h) represent two fusion proteins with the nonantibody partner fused to the amino-terminus of the C_H1 domain (g) or immediately before the hinge (h).

An alternative approach is to construct antibody fusion proteins with the ligand fused to the amino-terminus of the heavy chain (Fig. 8 d–f). This may be necessary for proteins that require N-terminal processing or folding for activity such as nerve growth factor (NGF), the costimulatory molecule B7.1, and interleukin-12 (IL-12). In fact, antibody-NGF, antibody-(B7.1), and antibody-(IL-12) fusion proteins containing the ligand fused to the amino-terminus of the antibody retain both the ability to bind antigen and the activity of the nonantibody partner.

Nonantibody sequences can also be used to replace the V_H domain or the V_H-C_H1 domains (Fig. 8 g and h). These molecules, which lack the ability to bind antigen, have been called *immunoadhesins* because they contain an adhesive molecule linked to the immunoglobulin Fc effector domains. In these proteins, the fused moiety acquires antibody-associated properties such as effector functions or improved pharmacokinetics. An example is the tumor necrosis factor (TNF) receptor IgG fusion protein, which binds to TNF (a mediator of inflammation) and neutralizes its activity. In fact, this molecule has been demonstrated to be efficacious for the treatment of rheumatoid arthritis.

Although Fig. 8 shows the nonantibody partner fused to the heavy chain, it should be appreciated that the nonantibody partner can also be fused to the light chain. It is also possible to construct antibody fusion proteins that combine more than one kind of nonantibody partner at the amino- or carboxy-termini of the heavy and/or light chains. In addition, a nonantibody

molecule can be fused to an scFv molecule as described in Sect. 4.1. Moreover, two antibody Fc fragments can be genetically fused resulting in a molecule with novel biological properties. An example of this approach is the protein GE2, which is the product of the fusion between the Fc fragments of human IgG and human IgE (Fcγ–Fcε fusion protein). GE2 does not have an Fab and, as a consequence, is unable to target an antigen. However, GE2 was able to form complexes with both FcγRII and FcεRI, resulting in an inhibition of mast cell and basophil activation that results in the blocking of the anaphylaxis in transgenic mice expressing human FcεRIα. This approach has therapeutic potential in IgE- and FcεRI-mediated diseases such as allergic asthma, allergic rhinitis, chronic urticaria, angioedema, and anaphylaxis.

5 Expression Systems

A large variety of expression systems have been used for the production of genetically engineered antibodies and antibody fragments. These expression systems include bacteria, yeast, plants, baculovirus, and mammalian cells.

Antibody fragments are commonly expressed in bacteria and yeast. The bacterium *E. coli* is a frequently used expression system owing to its rapid growth and easy genetic manipulation. However, proteins expressed in *E. coli* are frequently insoluble and/or inactive, and refolding may be required to obtain functional fragments. Secretion of fragments into the bacterial periplasm or culture supernatant provides an alternative means to obtain the desired functional fragments without the need for refolding. Although the results are highly antibody-dependent, there are many examples in which the bacterial expression system is successful.

Complete functional antibodies have been most successfully expressed in mammalian cells, as these cells possess the mechanisms required for correct immunoglobulin assembly, posttranslational modification (glycosylation), and secretion. Posttranslational modifications can influence the biologic properties and effector functions, important considerations especially when the antibody is to be used for therapy. Examples of mammalian cells that have been successfully used to express properly assembled and glycosylated antibodies and antibody fusion proteins are the mouse myeloma cell lines P3X63Ag8.653, Sp2/0-Ag14, and NS0/1. These three myeloma cell lines have lost the ability to produce endogenous H and L chains and are derived from the parent myeloma. Antibodies produced in nonlymphoid cell lines such as Chinese hamster ovary (CHO), HeLa, C6, and PC12 are also properly assembled and glycosylated. Owing to the slower growth of mammalian cells, mammalian expression requires a longer time frame and higher costs than bacterial or yeast expression, but it is preferred when complete functional antibodies with proper glycosylation and disulfide bonds are required. Other expression systems that have been extensively used to produce complete functional antibodies include insect cells and plants. There is no ''universal'' expression system – each system has its advantages and disadvantages.

6 Conclusion

Rapid progress has been made in producing genetically engineered

antibodies. The ability to express foreign DNA in a variety of host cells has made it possible to produce chimeric, humanized, and human antibodies as well as antibodies with novel structures and functional properties in quantities sufficiently large for many applications including clinical therapy. The available experience suggests that antibody-based therapies can be successfully developed for use in clinical situations in which no alternative effective therapy is available. However, continued progress in the development of antibody-based therapies will require extensive research to further define the mechanism of antibody action and on how to optimally use the novel proteins with unique functional properties.

Keywords

Antigen
Any piece of a substance that can induce a specific immune response or reacts to a specific antibody or T cell.

Adhesion Molecules
Proteins, such as integrins, selectins, members of the Ig superfamily, or CD44, that mediate the binding of one cell to other cells or to the extracellular matrix.

Adjuvant
A substance that enhances the immune response to antigens and is therefore used in immunizations.

Activation
A process by which the immune system (e.g. T cells, B cells) is switched on to deal with an infection.

Costimulation
Secondary signals provided to T cells by costimulatory molecules (e.g. CD80, CD86) on antigen presenting cells. Regulated expression of costimulatory molecules allows T-cell activation in inflammation but not under healthy conditions.

CpG
Denotes a deoxynucleotide motif in bacterial DNA that differs in sequence and methylation state from mammalian DNA. It binds to and activates certain subsets of dendritic cells.

Danger
A term popularized by Matzinger, that covers the various signals from damaged tissues or from microbial products that trigger activation of dendritic cells.

dsRNA
Denotes double-stranded RNA, known as the genome of retro-viruses.

Endotoxin
Lipopolysaccharides (LPS) that are an integral part of the outer cell envelope membrane of gram-negative bacteria. They evoke toxic and pyrogenic effects and cause sepsis.

Epitope
Specific amino acid sequence of foreign or self-antigens that an antibody (B-cell epitope) or a T-cell receptor (T-cell epitope) recognizes, binds to, and reacts against.

Germinal Center
Sites in secondary lymphoid organs where activated B cells undergo proliferation, selection, maturation, and apoptosis.

HLA
Acronym for human leukocyte antigen, denoting the human MHC molecules.

Humoral Immunity
Immune response involving B cells that produce antibodies.

Immunoglobulin
A protein produced by a B cell that binds to a specific antigen leading to attack by the immune system.

LPS
Lipopolysaccharide (cf. endotoxin).

Lymphatic System
A network of vessels that is separate from the blood circulation. It includes the lymph nodes that are the command centers of the immune system.

MHC
Major histocompatibility complex – a gene cluster encoding MHC molecules, originally described as antigens responsible for transplant rejection. MHC molecules bind antigenic peptides in order to activate T cells in an antigen-specific manner.

Peptide
Short fragment of a protein. On binding to MHC molecules, it can activate T cells and thereby becomes antigenic.

Processing
Set of activities of an antigen presenting cell encompassing proteolysis of an antigen, generation of antigen peptides, peptide loading onto MHC molecules, and transport of MHC-peptide complexes to the cell surface.

T_{H1}
Helper T cells that produce high levels of IFN-γ and promote activation of macrophages.

T_{H2}
Helper T cells that produce IL-4, IL-5, and IL-I0 and promote eosinophil, B-cell, and mast-cell functions.

Tolerance
The failure of the immune system to respond to antigens.

Vaccination
Administering an antigen to generate long-term antibody or cellular immune responses or both.

Antigen presenting cells play a key role in the immune system as they are the only cells of the body that are able to trigger antigen-specific immune responses upon infection with foreign invaders. Three differentially specialized types of cells are in charge of this vital task: dendritic cells, macrophages, and to a certain extent, B lymphocytes. We are beginning to understand the molecular mechanisms of how these cells take up, process, and present antigens and how this translates into T-cell activation or silencing. This knowledge is fundamental for both our current concepts about how the immune system discriminates between self and nonself and for the development of novel vaccination strategies against diseases still threatening mankind.

1 Antigen-specific Immunity

Our environment is rich in microbes and parasites, a multitude of them being pathogenic to humans and/or to other mammals or vertebrates. The necessity of means to combat microbial invaders is evident and is accomplished through the presence of a functional immune system. One type of weapon was discovered by Behring and Kitasato at the end of the nineteenth century in the serum of rabbits immunized with diphtheria bacilli: the cell-free serum was capable of destroying diphtheria toxins, it was specific for diphtheria and remained effective in the organism of other animals – the breakthrough in immunizing against diphtheria. Behring and his colleagues named the serum components of this monumental discovery *antitoxins*. Later on they were named *antibodies*, and the agents able to induce the generation of antibodies became known as *antigens*.

An immune response can be antigen-specific, as in Behring's immunization experiments with diphtheria and tetanus toxins, but also antigen-nonspecific (Fig. 1). Nonspecific immunity is based on specialized cells, such as natural killer (NK) cells,

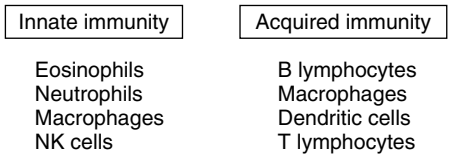

Fig. 1 Cells of the innate immune system versus cells of the acquired immune system. Eosinophils, neutrophils, macrophages, and natural killer (NK) cells confer innate immunity. B lymphocytes, macrophages, and dendritic cells are professional antigen presenting cells, often referred to as "APCs." They are the key players in facilitating acquired immunity.

eosinophils and neutrophils, and phagocytic cells, such as microglial cells in the brain or Kupffer cells in the liver. None of these elements require specific antigen recognition. These cells belong to the innate immune system. However, most pathogens cannot be eliminated by innate immunity alone but only through the involvement of elements of the adaptive or acquired immune system, which is antigen-specific. This system relies on antigen presenting cells that do not simply destroy antigens but expose their antigens on the surface for recognition by T cells. In particular, macrophages link the innate with the acquired immune system being both phagocytes and antigen presenters. Antigen exposure to effector T lymphocytes leads to production of antigen-specific antibodies, to cytolytic elimination of infected cells in an antigen-specific manner and/or to pathogen killing by phagocytosis. Thus, antigen presenting cells govern the initiation of both humoral and cellular immunity.

2
Antigen Presenting Cells (APCs)

2.1
The Discovery of Langerhans

In the second half of the nineteenth century, the histologist Langerhans was the first to detect a cell that immunologists nowadays call an *antigen presenting cell*. He used a gold impregnation method to stain skin sections and saw irregularly shaped cells with long protrusions reminiscent of dendrites of cutaneous nervous system cells. These cells formed a network of dendrites within the spinal layer of the epidermis and were called *Langerhans cells* (LCs). At the ultrastructural level, LCs can be identified by unique organelles in their cytoplasma, termed *Birbeck granules*. Birbeck granules are unique to LCs and allow us to distinguish them from macrophages and other dendritic cells. Almost a century later, LCs were rediscovered by immunologists and shown to function as APCs. Today, it is obvious that LCs are representatives of the dendritic cell family, specialized in trapping antigens that have penetrated the epidermis of the skin. Hence, they function as the sentinels of the antigen-specific skin immune response.

2.2
Professional APCs

The term APC refers to not only LCs but to all types of leukocytes that are responsible for taking up antigens at the entry sites of the body, transporting them to lymphoid organs where they recruit antigen-specific T lymphocytes (short: T cells). APCs thus act at the very beginning of an adaptive immune response. In order to mount such a response against an antigen that enters the body for the first time, APCs must be able to activate so-called *naive* T cells that

have not been stimulated before and "see" the respective antigen for the first time.

APCs that are able to prime naive T cells are termed *professional APCs* and include three sets of cells (Fig. 2): mononuclear phagocytes or macrophages, dendritic cells (DCs), and B lymphocytes (B cells). These three classes of APCs can be distinguished from nonprofessional APCs in that they express a specific combination of surface proteins that are critical for priming naive T cells. These surface proteins are (1) the gene products of the major histocompatibility complex (MHC): MHC class I and class II molecules bind peptides derived from antigenic proteins and present them to either cytotoxic T cells, characterized by the coreceptor CD8, or helper T cells expressing the coreceptor CD4, respectively; (2) the costimulatory molecules CD80 (B7.1) and CD86 (B7.2), which promote growth and differentiation of T cells upon engaging APCs; and (3) adhesion molecules such as ICAM-1 or LFA-3 that facilitate the primary contact between T cells and APCs.

DCs, although being highly diverse in origin and shape, appear to be the most potent professional APCs: DCs localize to all putative antigen entry sites of the skin, mucosa, and airways, they express high amounts of both classes of MHC molecules and, as members of the phagocyte family, they have an enormously high capacity to pino- and phagocytose antigenic material. Owing to their superior impact on the functionality of the acquired immune system, numerous attempts are ongoing to exploit DCs in immunotherapy of cancer and other diseases. Interestingly, about 100 years ago, the writer George Bernard Shaw stated in his famous book The Doctor's Dilemma: "There is only one genuinely scientific treatment for all diseases and that is to stimulate the phagocytes."

2.3 Nonprofessional APCs

One major prerequisite of bone marrow–derived professional APCs is their

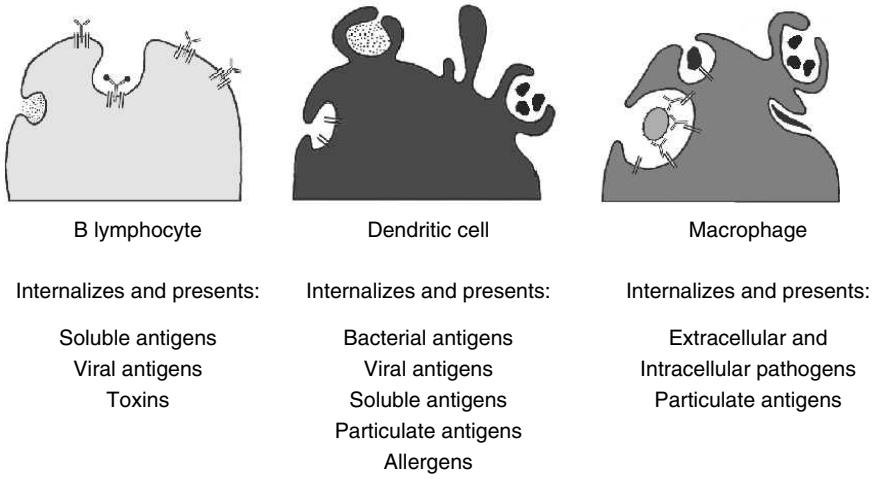

Fig. 2 The three types of antigen presenting cells (APCs). They have overlapping but distinct repertoires of antigens that they internalize, process and present to T cells.

Tab. 1 Nonprofessional APCs of the human immune system.

Cell type	*Constitutive MHC class I*	*Constitutive MHC class II*	*Costimulators CD80/CD86*
Thymic cortical epithelial cells	+	+	−
Thymic medullary epithelial cells	+	+	−
Keratinocytes	+	−	−
Myoblasts	+	−	−
T lymphocytes	+	−	−

concerted expression of MHC class II and costimulatory molecules CD80 and CD86. Apart from a very few exceptions, for example, vascular endothelial cells, only B cells, macrophages, and DCs are able to express reasonable amounts of CD80 and CD86 that are essential for activation of naive T cells. However, a number of other cell types can express MHC class II molecules (Table 1).

Thymic cortical epithelial cells (cTECs) that are critical for positive selection of $CD4^+$ thymocytes, and thymic epithelial cells of the medulla, which are responsible for deletion of self-reactive $CD4^+$ thymocytes, express MHC class II molecules in a constitutive fashion. The importance of MHC class II expression on cTECs is demonstrated by MHC class II–negative mutant mice that lack mature $CD4^+$ T cells. Following cytokine stimulation *in vitro* or during inflammatory states *in vivo*, MHC class II molecules are induced on a variety of epithelial and endothelial cells. IFN-γ induces MHC class II molecules in keratinocytes of the skin and even in myoblasts of muscles. Likewise, activated T lymphocytes in humans can become MHC class II positive.

It has been shown that cells becoming MHC class II–positive in the presence of proinflammatory cytokines, such as IFN-γ, are able to present peptides to $CD4^+$ T cells and to activate them, provided that the T cells do not need costimulation. Neo-MHC class II–expressing cells that have the potential to present antigen, are termed *nonprofessional* APCs.

3 Antigens Presented by APCs

3.1 Antigen Types

According to the initial definition brought up by the discoveries of Behring and Ehrlich, ''antigens'' are substances that cause the production of antibodies. However, this historic definition only covers humoral immune responses. Nowadays, molecules that are recognized by the antigen receptor of a B lymphocyte (B-cell receptor) and/or the antigen receptor of a T lymphocyte (T-cell receptor) are termed *antigens*. Antigens that initiate an immune response are named *immunogens*, whereas others may induce tolerance and are named *tolerogens*. Another subset of antigens that have a low molecular weight (<4000 Da) and are immunogenic only if they are covalently bound to a carrier protein, is termed *haptens*. Examples of haptens are substances, such as poison

ivy or penicillins, that bind covalently to proteins before or after take-up by APCs and then can cause allergy.

3.2 Biochemical Nature of Antigens

APCs are able to successfully present a large variety of organic substances (mainly consisting of carbon, hydrogen, oxygen, and nitrogen atoms); however, not a single inorganic substance is known to be able to trigger an antigen-specific immune response without the involvement of proteins. This is also true for large crystals, such as renal calculi. This clear difference in the immunogenicity indicates that the adaptive immune system evolved to circumvent the danger originating from organic and not inorganic material.

The most potent antigens are proteins and polypeptides. This is also true for polypeptides that consist of D-amino acids instead of naturally occurring L-amino acids. The reason for the strong immunostimulatory capacity is that proteins are easily recognized by the B-cell receptor and by (soluble) antibodies in the blood as well. In addition, proteins give rise to peptides during processing by APCs and peptides are the substances of choice to activate cellular immune responses through recognition by the T-cell receptor of T lymphocytes (Table 2).

Polysaccharides and glycans are by far weaker antigens than proteins. They can activate B cells but not T cells because APCs cannot present polysaccharides to T cells. Nevertheless, *Saccharomyces glycan* stimulates macrophages to secrete IL-1 and TNF-α, thereby supporting antitumor immunity in mice. Polysaccharides from bacteria, such as multiple branched glucose polymers (dextranes), induce strong antibody responses in humans and mice, however, not in rabbits or guinea pigs.

Most lipids are too small to act as antigens that induce antibody production. Similar to other low molecular weight substances, a few lipids can function as haptens, such as cardiolipin. Cardiolipin is a phospholipid derived from the mitochondrial membrane. It is released from cells upon bacterial infection with *Treponema pallidum*, binds to carrier proteins and, in this context, initiates formation of anticardiolipin antibodies (Table 2).

However, DCs such as LCs express CD1 molecules that bind and present certain lipids or glycolipids in order to induce T-lymphocyte activation. Nonglycosylated and glycosylated mycolates,

Tab. 2 Antigens presented by APCs via MHC and CD1 molecules, versus haptens.

Restriction	*Antigen*	*Hapten*
MHC class I/MHC class II	Proteins	Polysaccharides
	Polypeptides	DNA
	Peptides	Penicillin
	Glycopeptides	Cardiolipin
CD1	Mycolates	Organic substances
	Diacylglycerols	
	Sphingolipids	
	Polyisoprenoids	

diacylglycerols, sphingolipids, and polyisoprenoids derived from endogenous and microbial sources have been described (Table 2).

Similar to pure lipids, only DNA or RNA is widely unable to trigger generation of antibodies. Moreover, APCs obviously lack specialized receptors for DNA or RNA necessary for activating T lymphocytes. Nucleoproteins, however, are suitable to generate anti-DNA antibodies. Thus, DNA can serve as a hapten. Anti-DNA antibodies are actually found in the serum of patients suffering from the autoimmune disease systemic lupus erythematosus (SLE). Some of these antibodies react with denatured DNA, others with intact double-strand DNA.

3.3 Origin of Antigens

Under normal circumstances, the immune system relying on APCs reacts only against foreign antigens, but not against self-antigens. In cases in which a foreign antigen is a homolog of a self-antigen, the extent of the immune response decreases with increasing similarity between both antigens. To take this rule into account, transplantation immunologists differentiate between the donor and the recipient of a transplanted organ: antigens derived from a recipient of the same species are called *alloantigens*. When the antigen is derived from another species, it is named *xenoantigen*. In contrast to that, *autoantigens* are derived from the same organism and may cause autoimmune diseases.

4 Antigen Entry Sites

Vertebrates offer microbes a large interface to enter the body. Consequently, the lymphatic system is organized in such a way that lymphoid tissues are located in close proximity to all putative entry sites. Afferent lymphatic vessels drain fluid and APCs from the skin and from other peripheral tissues to the lymph node. The spleen filters antigen mainly from the blood stream. The gut-associated lymphoid tissues (GALT), which include the tonsils, adenoids, appendix, and the Peyer's patches (PP) in the small intestine, collect antigen from the epithelial surfaces of the gastrointestinal tract.

Likewise, the bronchial-associated lymphoid tissues (BALT) and the mucosal-associated lymphoid tissues (MALT) protect the respiratory epithelia and other mucosa respectively. Each of these lymphatic tissues traps foreign antigens through the activity of migratory APCs that present antigenic peptides to T lymphocytes, thereby initiating antigen-specific immunity. Importantly, even in the absence of foreign antigen, lymphoid tissues provide signals to lymphocytes via presentation of self-antigens. This is important for the survival of naive and silent T lymphocytes, thereby contributing to the maintenance of T-cell homeostasis.

4.1 APCs in the Skin

Antigen that has penetrated the epidermis is primarily picked up by LCs. LCs are derived from monocytes that leave the blood stream and migrate into the epidermis where they adopt the shape of typical DCs. Antigen-fed LCs leave the skin and migrate as so-called *veiled cells* via the afferent lymph vessels to the draining lymph nodes. There, they accumulate as interdigitating dendritic cells (IDCs) in the T cell–rich areas.

Under pathological conditions, for example, in skin suffering from the autoimmune disease psoriasis, not only LCs but also keratinocytes express high amounts of MHC class II molecules and become capable of functioning as APCs. In other squamous epithelia, DCs different from LCs do occur. This is true of the oral and nasal mucosa, the trachea and bronchus, and the esophagus and the tonsils. In the epithelia lining the lung, the stomach, and the gut, DCs have not been found, as yet.

4.2 APCs in the Mucosa

Although tight junctions and the mucous layer of mucosal surfaces widely exclude microbes and large particulate antigen(s), antigenic proteins are known to surpass this barrier through endo- and transcytosis. Granulocytes, as representatives of the innate immune system, and macrophages functioning as APCs take up these antigens in the lamina propria. Furthermore, in the gut and bronchus, an antigen transfer system exists that transports antigens from the lumen to the GALT and BALT respectively. A prerequisite of this system is the presence of a specialized type of epithelial cell, the so-called *M cell* (see below).

4.3 APCs in the Gut

The uptake of bacteria, proteins, and abiotic substances (e.g. latex) by the Peyer's patches and by lymphoid follicles in other parts of the gut, for example, the appendix, is well known. The GALT is separated from the gut lumen by a single layer of epithelium, containing M cells (Fig. 3). In ultrathin sections, an M cell is seen as a rim of apical cytoplasm that bridges the space between two adjacent epithelial cells. An M cell forms a kind of an umbrella above a space surrounded by epithelial cells and filled with all sorts of APCs including DCs, macrophages, and B cells. Thus, antigen from the gut lumen is transcytosed through the epithelial monolayer and

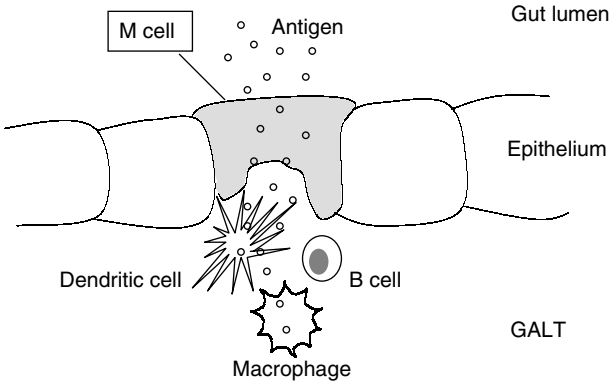

Fig. 3 The gut-associated lymphoid tissue (GALT). Antigens from the gut lumen traverse the single layer of epithelia via M cell–mediated transcytosis whereupon they get in contact with APCs (dendritic cells, macrophages, B cells) of the GALT. APCs are very similarly organized in the lymphoid tissues of the bronchus and Waldeyer's ring.

reaches APCs, which take up and process the antigen and present it to T lymphocytes in the PP or in mesenteric lymph nodes.

4.4 Antigen Uptake in the Respiratory Tract

In the upper respiratory tract, antigen presenting LCs occur in the transitional zones between the keratinizing epithelium of the skin and the mucosal surface of the nasal cavity and the nasopharyngeal region, for example, the lips. Moreover, APCs fulfill their sentinel function in and around the lymphoid tissue of Waldeyer's ring. The epithelium above the ring of Waldeyer contains, just as BALT and GALT do, antigen transporting M cells. Furthermore, DCs are found in the epithelium of the trachea. The rest of the mucosal surface of the upper respiratory tract serves to exclude rather than take up antigen.

Antigen exclusion is also dominant in the lower respiratory tract, in particular, the lung. Antigen clearance mainly depends on mucociliary activity of the epithelia and/or alveolar macrophages. Macrophages in the alveoli act as both phagocytic cells of the innate defense system and as APCs giving rise to acquired immunity. Some of them simply phagocytose and digest foreign antigens involving the lung; others stimulate a local immune response. For this purpose, alveolar macrophages loaded with antigen cross the lining of the alveoli and migrate into lymph nodes located in the lung tissue. Thus, similar to DCs, alveolar macrophages form a lung-specific antigen handling system.

5 Antigen Presenting Molecules

Both types of the classical molecules of the MHC, class I and class II, are peptide receptors and encoded by genes that display the highest degree of polymorphism in the genome. Within the MHC molecules, the polymorphism is mainly restricted to the regions that constitute the antigenic peptide-binding cleft. The advantage of the multitude of MHC alleles encoding for a multitude of distinct peptide-binding specificities is that there will be hardly any foreign peptide that cannot be bound by at least a few individuals of a population. In contrast, CD1 molecules are MHC class I–like receptors for mycobacterial lipids or glycolipids. They are not encoded in the MHC and are monomorphic. Their physiological role is, as yet, ill defined.

5.1 MHC Class I Molecules

MHC class I molecules are glycosylated transmembrane proteins that consist of two subunits: the larger α-chain encoded in the MHC genetic locus is polymorphic and forms the peptide-binding site. It associates with the smaller subunit, β_2-microglobulin (β_{2m}), which is nonpolymorphic and encoded outside the MHC. β_{2m} and the membrane-proximal α_3-domain of the α-chain fold as immunoglobulin domains, whereas the membrane-proximal (membrane-distal) α_1- and α_2-domain constitute the peptide-binding cleft (Fig. 4).

Quite in contrast to other peptide receptors described in the hormone system, the binding cleft of MHC molecules is highly promiscuous so that a large variety of antigenic peptides can be presented. In the case of MHC class I molecules, this peculiarity is accomplished through three structural criteria shared by peptide ligands: (1) the peptide length is limited to 8 to 10 amino acids, with the majority

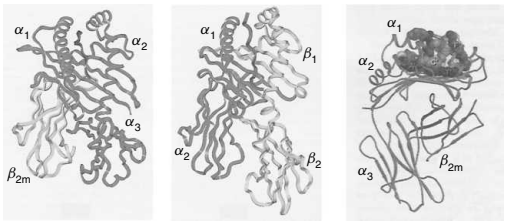

Fig. 4 X-ray structure of the MHC class I molecule HLA-Aw68, the MHC class II molecule HLA-DR1, and the CD1b molecule, which are key surface molecules of APCs. Adapted from Guo, H. C. et al. of peptides being 9-mers; (2i) 1 to 2 side chains of the peptide, called *anchors,* fit into corresponding specificity pockets in the binding cleft. Both the position and identity of these anchor residues vary, depending on the particular MHC class I molecule (allele-specific anchor motifs); and (3) the amino- and carboxyterminni of peptides are fixed in the binding cleft through a hydrogen-bonding network.

To illustrate this in more detail, the sequences of self- and foreign peptides restricted by the human MHC class I molecule HLA-A2 are compared (Table 3): 70% of these peptides are 9-mers with a leucine or methionine at the anchor position P2 and a valine at the anchor position P9. Owing to the fact that the sequences at the nonanchor positions are widely irrelevant for binding, more than

500 different peptides have been estimated to constitute the self-peptide repertoire of HLA-A2 expressed on the surface of a B cell; however, none of these peptides binds to HLA-A1 and vice versa. The reason is that HLA-A1 and HLA-A2 differ strongly in the anchor motif of their peptide ligands.

Today, more than 220 distinct HLA-A and more than 450 distinct HLA-B type alleles are known. Not all of the alleles have distinct anchor motifs, however, the high diversity of allelic MHC products observed in the human population allows a high diversity of self- and foreign peptides to be bound. This strategy reduces the risk that some pathogens may escape recognition by the immune system due to holes in the binding capacity of MHC molecules.

5.2 MHC Class II Molecules

The crystallographic structure of MHC class II molecules shows that they are folded very much like MHC class I molecules, although class II dimers consist of a noncovalent complex of an α- and a β-chain, which are both encoded within the MHC. Again, highly polymorphic regions are located in the peptide-binding cleft, consisting of 8β-strands and 2α-helical segments that serve to sandwich peptide ligands (Fig. 4).

The only and decisive structural difference is that the class II binding cleft is open at both ends, whereas the class I cleft is closed. A critical consequence is that naturally processed peptides binding to class II MHC molecules are at least 12 to 14 amino acids long and can be much longer. The majority of class II–associated peptides are 15- to 17-mers. The binding forces of the class II peptide-binding cleft are distributed to 3 to 4 specificity pockets, most often localized at relative positions P1, P4, P6, and P9 (Table 4). Moreover, about a dozen hydrogen bonds contacting the whole backbone of a typical 15-mer stabilize the class II–peptide interaction. In further contrast to class I molecules, the specificity pockets of the class II groove are more permissive, often allowing 3 to 5 structurally similar amino acid side chains to fit into a particular pocket (Table 4).

The advantage of this peculiarity is that class II molecules encoded by the same MHC class II allele are able to accommodate a large repertoire of different peptide sequences. This may be viewed as an adaptation to pathogens that constantly change their immunodominant antigens by high mutation rates. The disadvantage is that MHC class II allele-specific peptide ligand motifs are rather complex and class II–restricted immunodominant epitopes are difficult to predict.

5.3 CD1 Molecules

CD1 molecules are nonpolymorphic transmembrane glycoproteins encoded by genes outside the MHC. The overall structure of CD1 is similar to that of MHC class I molecules in that CD1 molecules form heterodimers of ~45-kDa heavy chains associated with β_{2m}. However, unlike MHC class I molecules, CD1 is not retained within the endoplasmic reticulum but is targeted at endocytic compartments where it binds its ligands. CD1 molecules are expressed only on dendritic cells, monocytes, and some thymocytes. Like classical MHC class I and class II molecules, CD1 molecules are recognized by T cells. However, unlike classical MHC molecules, group I CD1 molecules (CD1a, CD1b, CD1c), which are found in humans but not in mice, present mycobacterial lipids, mycolic acids, lipoarabinomannan,

phosphatidylinositol mannosides, and hexosyl-1-phosphoisoprenoids to cytotoxic T cells. These ligands are derived either from internalized mycobacteria or from the uptake of lipoarabinomannans by the mannose receptor expressed on the surface of monocytes and dendritic cells. No naturally processed bacterial antigens have been identified in the context of the group II molecule CD1d molecule, which is expressed in both humans and mice. CD1d molecules present bacterial α-galactosylceramide to NK T cells. The relationship between the peptide- and lipid-binding capacities of CD1 is not clear, as yet. Structural studies show that CD1 molecules bear a deep and hydrophobic ligand-binding cleft in which glycolipids bind – it is open whether peptides associate to the same site (Fig. 4).

Compared to MHC class I and class II molecules, CD1 proteins appear to represent a separate lineage of antigen-presenting molecules specialized in presenting microbial lipids, glycolipids, and a subset of peptide antigens to T cells.

6 Antigen Processing by APCs

Virus-infected cells can be destroyed by $CD8^+$ cytotoxic T cells provided that the

respective cells present viral peptide antigens bound to MHC class I molecules on their cell surface. Likewise, exogenous foreign antigens that are pino- or phagocytosed by APCs at sites of inflammation lead to activation of $CD4^+$ helper T cells when APCs present antigen-derived peptides in the context of MHC class II molecules. The concept that foreign antigenic peptides stimulate T cells only in the context of MHC molecules has been introduced by Zinkernagl and Doherty as *MHC restriction*. The conversion of protein antigens derived from the extracellular space or the cytosol into peptides and the conservation of this antigenic information through loading onto MHC class II or class I molecules is accomplished by pathways of antigen processing.

The different fates of vesicular and cytosolic antigens are mainly due to the segregated pathways of biosynthesis and assembly of class I and class II molecules. Both pathways, however, have evolved as adaptations of basic cellular functions, such as endocytosis, transmembrane transport, and protein degradation, which are not exclusively used for antigen presentation.

6.1 MHC Class I Processing Pathways

The peptide-receptive binding cleft of class I molecules is localized on the luminal side of the ER. Class I–restricted antigenic peptides, however, are derived from cytosolic or nucleic protein antigens. Therefore, accessory molecules are necessary for antigen processing. IFN-γ increases the expression of these accessory molecules and MHC class I molecules (Fig. 5).

6.1.1 Generation of Peptide Ligands

The majority of antigenic peptides presented by MHC class I molecules appears to be generated by the multicatalytic proteinase complex, named the proteasome. The proteasome is localized in the cytosol and nucleus and consists of 28 subunits that form a central channel where unfolded polypeptides are cleaved into short peptides (Fig. 5). In the presence of IFN-γ, the catalytic activity of the proteasome changes due to the replacement of 3 constitutive subunits for the new subunits LMP2, LMP7, and MECL-1. The proteasome containing these new subunits is called the immunoproteasome and preferably generates peptides with a C-terminal hydrophobic or basic amino acid. Peptides with these structural features are superior to other peptides with regard to binding to MHC class I molecules.

Apart from the proteasome, other proteases and peptidases are involved in processing of antigens in the MHC class I pathway: cytosolic calpains and aminopeptidases are sometimes required, the actual involvement being strongly influenced by the type of antigen to be cleaved. Moreover, the ER-resident aminopeptidase ERAP-1 has recently been described to be mainly responsible for N-terminal trimming of precursor peptides, thereby giving rise to typical 8-mer, 9-mer, and 10-mer epitopes.

6.1.2 TAP

The transporter associated with antigen processing (TAP) belongs to the ABC family of heterodimeric transmembrane transporters, which are fueled by ATP hydrolysis. TAP is localized in the membrane of the ER and shuttles peptides of variable length ($n = 6$ to 30 amino acids) from the cytosol into the ER lumen (Fig. 5). This is a prerequisite

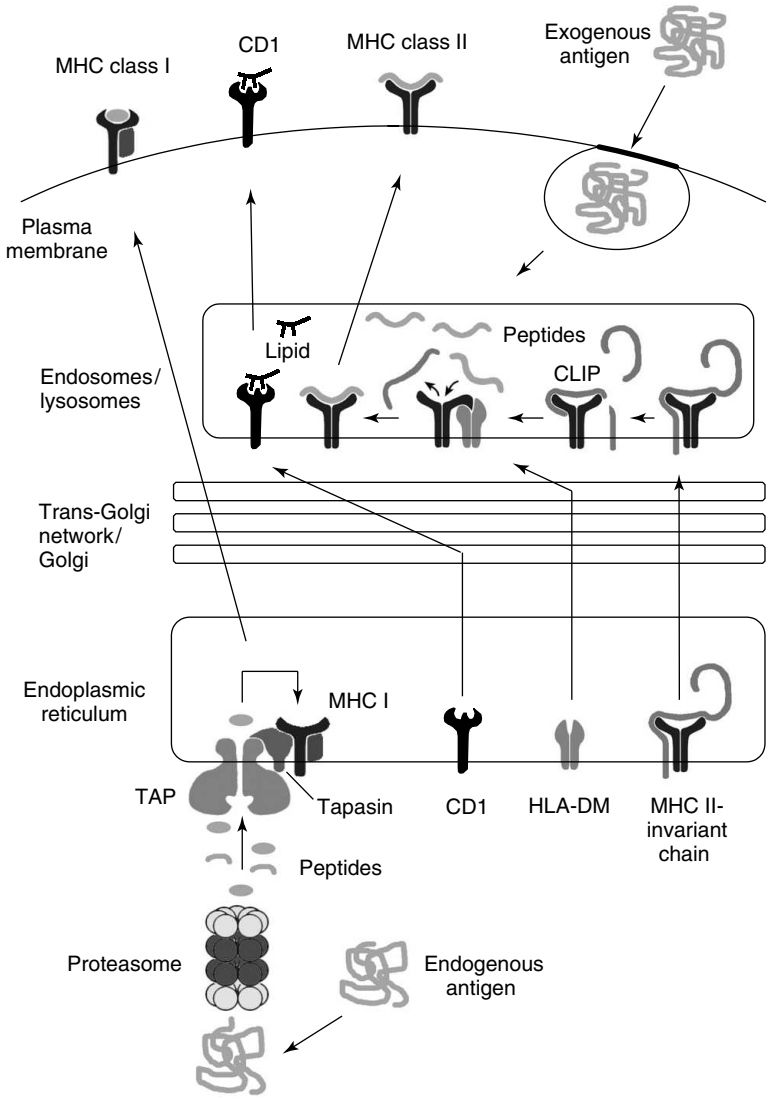

Fig. 5 Antigen processing pathways leading to the generation of MHC class I-peptide, MHC class II–peptide, and CD1-lipid complexes.

for the regular supply of MHC class I molecules with peptide antigen. Moreover, TAP is an essential constituent of a multimolecular peptide–loading complex in the ER that regulates loading of MHC class I molecules with cognate antigenic peptides.

6.1.3 **The MHC Class I Loading Complex**

Newly synthesized MHC class I heavy chains (α) are stabilized by binding to the chaperone calnexin until the heavy chain forms dimers with β_2-microglobulin (β_{2m}). After dissociation of calnexin, the chaperone calreticulin allows α:β_{2m}

complexes to enter a multimolecular loading complex, which is responsible for the formation of cognate class I-peptide complexes. Constituents of this loading complex are α:β_{2m}, calreticulin, TAP, the protein-disulfide-isomerase ERp57, and the TAP-associated chaperone tapasin (Fig. 5). During peptide loading, ERp57 gives allowance for the regulated opening and closing of a disulfide bond in the binding cleft domain of the class I heavy chain. Tapasin bridges TAP and α:β_{2m}, and retains peptide-free α:β_{2m} dimers in the ER until a stably binding peptide occupies the groove. Consequently, preferentially long-lived α:β_{2m}-peptide complexes leave the ER and make it to the cell surface. Thus, tapasin is thought to function as a peptide editor, similar to HLA-DM in the MHC class II processing pathway (see below).

6.2 MHC Class II Processing Pathways

MHC class II-associated peptides originate from two sources: endocytosed exogenous antigens or endogenous self-antigens, the majority of them being membrane proteins derived from endosomes or the nucleus (Table 4).

6.2.1 Endosomal Generation of Peptides

Professional APCs are equipped to internalize whole pathogens, for example, bacteria or viruses, small vesicles, multimolecular complexes, proteins or peptides via phagocytosis, pinocytosis or in a receptor-mediated fashion. In all these cases, endocytosed antigens end up in endosomal compartments, known for their low pH and the high redox potential (Fig. 5). These conditions favor denaturation of protein antigens and proteolytic generation of peptides via hydrolases, amino- and carboxypeptidases, and endopeptidases. Endosomal/lysosomal compartments of APCs, which are enriched in MHC class II molecules, as determined by electron microscopy or immunohistochemically, have been termed *MIICs* (MHC class II compartments).

6.2.2 Invariant Chain and CLIP

The invariant chain (Ii) is a chaperone dedicated primarily to MHC class II molecules. In DCs, Ii also binds to CD1 molecules. In general, Ii trimers bind to newly synthesized class II $\alpha\beta$ dimers, allowing them to obtain their native conformation. Since Ii binding blocks the sole peptide-binding cleft, Ii-associated class II molecules cannot bind antigens. Owing to a targeting signal in the cytosolic tail of Ii, Ii class II complexes are sorted from the trans-Golgi-network directly to endosomal/lysosomal MIICs (Fig. 5).

In MIICs, Ii is proteolytically degraded whereas $\alpha\beta$ dimers remain intact. The proteases mainly responsible for Ii degradation are cathepsin S in DCs and B cells and cathepsin L in cortical epithelial cells. The terminal Ii fragment that still occupies the peptide-binding cleft of class II molecules is termed *CLIP* (class II MHC-associated Ii peptide). Under steady state conditions, CLIP is part of the self-peptide repertoire of class II molecules. Since it dissociates from the majority of class II allelic proteins rather slowly, CLIP has to be actively removed from the class II binding cleft.

6.2.3 HLA-DM

HLA-DM (termed H2-M in mice) is a nonclassical MHC class II protein, displaying 20 to 25% sequence homology to both classical class I and class II molecules. X-ray analysis revealed that HLA-DM lacks

a peptide-binding groove and, thus, is unable to function as an antigen-presenting molecule. It bears a targeting signal for MIICs where it accumulates and transiently engages in complexes with classical class II MHC molecules. HLA-DM has three important functions (Fig. 5): (1) it catalytically removes the Ii-derived precursor peptide CLIP, thereby promoting peptide loading; (2) it remains bound to empty class II molecules and prevents their unfolding as a molecular chaperone; and (3) it functions as a peptide editor, as it removes peptides that bind with low kinetic stability to class II dimers. Consequently, preferentially high-stability class II peptide complexes are displayed on the surface of APCs, as long as these cells bear sufficient HLA-DM. This principle allows APCs, once loaded with cognate antigen, to activate $CD4^+$ T cells for prolonged periods of time, even a couple of days after encounter of antigenic material.

6.2.4 Tetraspan Network

Professional or nonprofessional APCs and even T cells express proteins, such as CD9, CD37, CD53, CD63, CD81, CD82, and CD151, belonging to a family termed *tetraspan proteins* or *tetraspanins*. The nomenclature relates to the fact that all of them traverse the membrane four times. It is well established that they are able to form homo- and heterodimers and thus form two-dimensional networks in the membrane. In APCs, tetraspanins form clusters with various integrins and MHC molecules. In MIICs, CD82 and CD63 associate with HLA-DM and classical class II molecules. On the cell surface, CD81, CD9, and CD53 form microdomains together with MHC class II and class I molecules. The function of tetraspan microdomains may be to increase the local density of MHC class II peptide complexes in loading compartments and on the surface, so that the avidity of an APC–T cell encounter is increased, thereby raising the efficacy of T-cell activation.

7 Activation of T Cells by APCs

After leaving the thymus, mature T cells recirculate between blood and peripheral lymphoid tissue until they recognize an MHC-peptide complex on the surface of an APC. T cells that have not yet been activated via encounter of an antigen are termed *naive T cells*. In contrast, T cells that have already contacted MHC molecules carrying foreign peptide antigens start to proliferate and differentiate into cells capable of contributing to the removal of the antigen. They are termed *effector T cells*.

Effector T cells can be subdivided into three classes, according to the type of pathogen that may skew the efficiency of peptide entry into different processing pathways. Peptides from pathogens that multiply in the cytosol, such as influenza virus, vaccinia, and *Listeria monocytogenes*, are presented by MHC class I molecules and activate $CD8^+$ cytotoxic T cells that kill infected target cells. Pathogens that accumulate in endosomal vesicles of macrophages, such as mycobacteria or *Leishmania*, facilitate the differentiation of T_{H1} helper cells that express Fas ligands enabling them to kill infected macrophages. Extracellular antigen derived from viruses tend to stimulate the production of T_{H2} helper cells that initiate a humoral immune response by activating naive B cells to produce neutralizing IgM antibodies.

The activation of naive T cells following engagement with MHC–peptide complexes in APCs constitutes a primary

immune response. In the case of such a primary response, a subset of long-lived T cells is generated that gives an accelerated response upon seeing the same antigen for the second time. These T cells are called *memory T cells*. Memory T cells differ in several instances from naive T cells, but like naive T cells they require activation by professional APCs in order to become effector T cells.

Finally, it has been shown that T cells need to contact APCs continuously in order to stay alive. This is accomplished by the recognition of MHC-self-peptide or MHC-foreign peptide complexes on the surface of APCs.

7.1 Cell Adhesion Molecules

The migration of naive T cells through lymph nodes and their initial contacts with APCs depend on interactions that are not antigen-specific, hence are independent from MHC-peptide complexes. The initial cell–cell contact between APCs and T cells is controlled by an array of adhesion molecules on the surface of T cells that recognize a complementary array of adhesion molecules on the surface of an APC. The main classes of adhesion molecules are the selectins, the integrins, members of the Ig superfamily, and mucin-like molecules.

Selectins are particularly important for the T cell homing into particular tissues. For example, L-selectins on the T-cell surface binds to addressins, such as CD34 or MAdCAM-1, on vascular endothelial cells.

To guide naive T cells to DCs, chemokines play a role: the chemokine MIP-3β directs naive T cells and mature DCs into lymphoid tissues. Moreover, DCs in lymphoid tissues express the chemokine SLC (secondary lymphoid tissue chemokine) that binds to the chemokine receptor CCR7 expressed on naive T cells. This event obviously reinforces the strength of successive T cell–DC interactions mediated via integrins and proteins of the Ig superfamily.

Integrins are heterodimeric cell surface proteins, consisting of a large α-subunit and a smaller β-subunit. There are several subfamilies of integrins broadly defined by their common β-chains. An important integrin expressed mainly by T cells, but also by macrophages, is LFA-1 (lymphocyte function-associated antigen-1), an $\alpha_L\beta_2$ integrin. LFA-1 mediates migration of both naive and effector T cells out of the blood and the initial contact with DCs. Another integrin VLA-4 (very late activation antigen-4), which is particularly strongly expressed by activated effector T cells, and the Ig family member CD2 function as substitutes for LFA-1. The majority of cell surface adhesion molecules being involved in T cell–APC interactions are members of the Ig superfamily. Three very similar intercellular adhesion molecules (ICAM-1, ICAM-2, ICAM-3) bind to the integrin LFA-1. ICAM-1 (CD54) and ICAM-2 (CD102) are expressed on APCs and on epithelia, whereas ICAM-3 (CD50) is only expressed on T cells and B cells. In addition to binding to LFA-1, ICAM-3 has a high affinity for the lectin DC-SIGN (DC-specific ICAM-3-grabbing nonintegrin; CD209), which is only found on DCs. The ICAM-3/DC-SIGN interaction appears to be exclusive to the contact between naive T cells and DCs, whereas CD2 binding to LFA-3 synergizes with LFA-1 binding to ICAM-1 and ICAM-2 on all types of APCs.

Importantly, it turned out that the strength of the LFA-1/ICAM interaction of a naive T cell and an APC depends on the type of MHC–peptide complexes

being presented by the APC; in those cases in which the T cell recognizes a cognate MHC-peptide ligand, a conformational change in LFA-1 increases its affinity for ICAM-1 or ICAM-2 of the APC. This phenomenon allows that the T cell–APC contact can persist for several days, so that a naive T cell can proliferate and become an effector T cell. In the majority of encounters, the T cell will not recognize an appropriate peptide antigen and separates from APCs, keeping on migrating through the lymph node. Thus, the transient nature of binding of naive T cells to APCs via adhesive interactions is crucial in the sampling of large numbers of MHC molecules and APCs.

7.2 Costimulatory Molecules

MHC–peptide complexes expressed on APCs are recognized by ligation of a corresponding T-cell receptor on the T-cell side. This interaction can be viewed as a first signal and it is critical for the antigen-specificity of a cellular immune response. However, in order to trigger clonal expansion and differentiation of a naive T cell, a second or costimulatory signal delivered by the same APC is required.

The best-studied costimulatory molecules solely expressed by APCs are B7.1 (CD80) and B7.2 (CD86). Both are homodimeric members of the Ig superfamily. Both B7 molecules share a common receptor on T cells, CD28. Ligation of CD80 or CD86 by CD28 costimulates the clonal expansion of naive T cells. Lack of B7 molecules abrogates T-cell proliferation.

Other costimulatory molecules on APCs are the TNF family member CD40 and 4-1BBL, which bind to CD40 ligand and 4-1BB (CD137) on the T-cell side, respectively. Both pairs of molecules are induced upon B7/CD28-mediated activation and function in sustaining the development of a full T-cell response. Notably, not only does the T cell receive a signal via the CD40/CD40L engagement but the APC also receives a signal. The best-characterized case is the conditioning of developing DCs via the engagement of activated $CD4^+$ helper T cells, so that the DC gains the capacity to fully activate $CD8^+$ cytotoxic T cells (''license-to-kill model''; cf Sect. 10.5.1.).

Activated T cells express an additional receptor for B7 molecules, denoted as CTLA-4, a homolog of CD28. However, CTLA-4 has a manyfold higher affinity to B7 than CD28 and transmits an inhibitory signal to T cells. Thus, CTLA-4 upregulation on the surface of T cells serves to downregulate proliferation and cytokine secretion of activated T cells.

A further CD28-like costimulator is ICOS, which recognizes LICOS produced on activated B cells, monocytes, and DCs. ICOS is poorly investigated so far – it is only known to induce IL-10 secretion of activated T cells.

The physiological relevance of the involvement of costimulatory molecules is to prevent destructive immune responses in the absence of signals mediated by pathogens, for example, responses against self-tissues. This is accomplished through the limitation that APCs express costimulatory B7 molecules only upon receiving danger signals from bacterial or viral products or equivalent proinflammatory signals. Consequently, naive T cells become effector T cells only when they receive signal 1 and signal 2 from the same APC. When signal 2 is lacking, the T cell is rendered anergic. Anergy means that the T cell becomes refractory to signals, even when signal 1 has been sent by professional APCs.

7.3 The Immunological Synapse

High-resolution confocal microscopy revealed that the key molecules involved in the formation of heterotypic junctions between APCs and T cells are reorganized in a highly characteristic manner. This specialized junction that results from cytoskeleton-driven clustering of MHC-peptide complexes, T-cell receptor molecules, adhesion molecules, and costimulators has been termed the *immunological synapse*. It is the close apposition of two membranes and the peculiar shape of the T cell that is reminiscent of neurological synapses (Fig. 6).

The immunological synapse consists of two concentric rings. In the center, proteins of the so-called central supramolecular activation cluster (c-SMAC), such as the T-cell receptor (TCR), CD2, CD3, the costimulator CD28, the protein kinases lck, fyn, and PKC-θ cocluster on the T-cell surface. Complementarily, MHC-peptide complexes and the costimulator CD80 have been described to cluster in the c-SMAC zone of APCs. The c-SMAC is surrounded by a second zone, the peripheral supramolecular activation cluster (p-SMAC). On T cells, the p-SMAC contains the integrin LFA-1 and the cytoskeletal protein talin. Accordingly, the adhesion molecule ICAM-1, known to be a ligand of LFA-1, coalesces in the p-SMAC of APCs.

The p-SMAC provides adhesive anchoring of the T cell to the APC, whereas the c-SMAC represents a protected zone for sustained signaling via the TCR. Immunological synapses are maintained for at least 1 h. Outside the p-SMAC is a third area containing proteins that are excluded from the synapse, such as the mucin CD43 or the phosphatase CD45. Exclusion of both types of proteins from the T cell–APC contact area is essential, as both molecules are very large and would therefore prevent

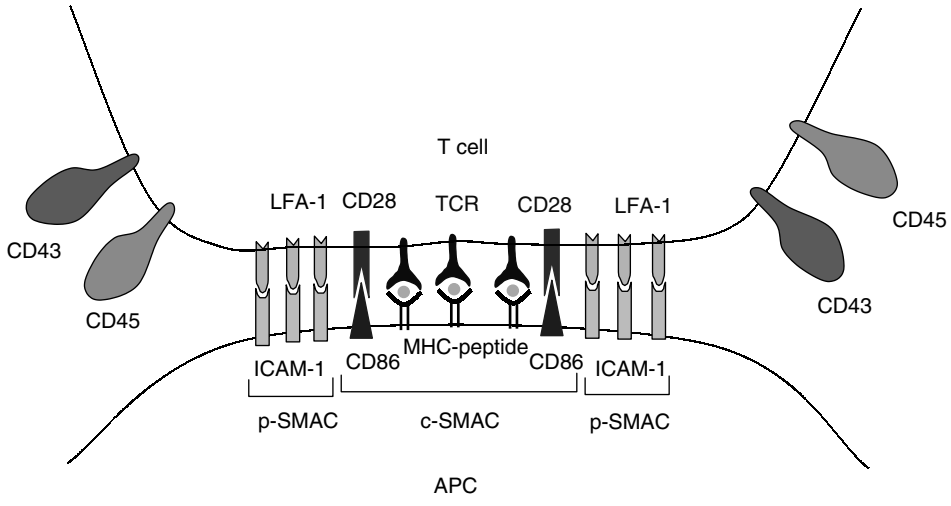

Fig. 6 The immunological synapse between a T cell and an APC. In the central zone (c-SMAC), MHC-peptide complexes, costimulators, for example, CD86, TCRs, and CD28 accumulate. In the surrounding ring zone, termed p-SMAC, the adhesion molecules ICAM-1 and LFA-1 are found. Excluded are large molecules, for example, CD43 and CD45.

small molecules, such as the TCR and MHC molecules, from interacting with each other.

Exploratory adhesive interactions of T cells and APCs precede formation of the synapse. The adhesion molecule ICAM-3 has been reported to initiate antigen-independent scanning of the APC surface by T cells followed by early signaling events and rearrangements of the T cellular cytoskeleton. The synapse itself appears to be a highly dynamic structure. At the beginning, cognate TCR ligands localize to an outermost ring of the nascent synapse, whereas LFA-1 and ICAM-1 constitute the c-SMAC. After 5 to 10 min, ICAM-1 moves to the p-SMAC and MHC-peptide clusters concentrate at the heart of the synapse. Finally, the coreceptor CD4 progressively migrates out of the c-SMAC in the course of synapse maturation. Strikingly, synapses between naive $CD4^+$ or $CD8^+$ T cells and DCs can form in the absence of antigen or MHC molecules. This finding underscores the fact that the synapse is a flexible rather than a static entity. In conclusion, the immunological synapse can be viewed as a platform that favors interactions between costimulatory molecules, such as CD28, thereby facilitating priming of naive T cells.

8 Macrophages

Macrophages belong to the first line of innate defense to protect the vertebrate body from invasive microorganisms. When a microorganism crosses an epithelial barrier and replicates in a host tissue, it is rapidly recognized by mononuclear phagocytes, or macrophages. Macrophages differentiate from monocytes that leave the blood circulation to migrate into tissues throughout the body. Together with neutrophils, macrophages are key players of the innate immune response because they are equipped to recognize, ingest, and destroy many pathogens without the aid of an adaptive immune response. It is noteworthy that macrophages endocytose the equivalent of their entire cell volume in about 30 min and, on the other hand, secrete more distinct products than even hepatocytes, which secrete numerous serum proteins.

As macrophages react very rapidly on encountering an infecting microorganism, and since the immune system of invertebrates relies entirely on macrophage-driven innate responses, in the early 1960s, Elie Metchnikoff believed that the same would be true for vertebrates. In the meantime, we know that macrophages are of superior importance in the nonadaptive branch of our immune system, but play a less dominant role in mounting an adaptive immune response, since they express comparably low amounts of MHC and costimulatory molecules. Nevertheless, they do cross talk extensively with B and T cells and may be very important for targeted effector T-cell functions in the context of infected cells.

8.1 Evolutionary and Cellular Origin

Macrophages in culture behave very similar to amoeba feeding on microorganisms. From this and other similarities, it was concluded that the amoeba is one of the earliest or the earliest form of a phagocytic cell or macrophage. The evolutionary pathway from the ancient amoeba to the modern macrophage is unknown. However, the urgent need for an amoeba to distinguish between other amoeba that

should be left untouched and nutrient microorganisms that should be engulfed and degraded, is obvious. Hence, any surface receptor that allowed the amoeba to specifically recognize food would have been a great evolutionary progress. Such a receptor could have been the ancestor of a pattern-recognition receptor (PRRs). Such PRRs have originally been proposed by Janeway. They could serve in distinguishing bacteria or viruses, which carry regularly organized membrane or coat proteins named *pathogen-associated molecular patterns* (PAMPs) from self-proteins, which are not organized in such patterns. In the meantime, equivalents of PRRs have been found: the family of Toll-like receptors (TLRs), which recognize various types of viral or bacterial substances, such as lipopolysaccharide (LPS) or dsRNA. And indeed, TLRs are expressed on macrophages and on DCs.

All vertebrates and many invertebrates have a population of phagocytic cells that patrol their bodies. Macrophages are found in higher vertebrates in especially large numbers in connective tissue, in association with the gastrointestinal tract, in the lung, where they are found in both the interstitium and the alveoli, along blood vessels in the liver (termed *Kupffer cells*), throughout the spleen, where they remove senescent blood cells, and in the thymus, where they aid in thymocyte education.

Beyond that, macrophages are also found at several strategically important locations in the lymph nodes. They are particularly enriched in the marginal sinus zones where the afferent lymph enters the lymphoid tissue, and in the medulla, where the efferent lymph collects before having access to the blood. Here, they obviously prevent antigens from entering the blood stream, a critical event, as otherwise sepsis would occur.

Irrespective of their tissue localization, they differentiate from bone marrow–derived monocytes, which are considerably smaller and not phagocytically active.

For targeting macrophages into sites of infection, macrophages bear low levels of chemotactic receptors, such as the f-Met-Leu-Phe or 7-transmembrane-α-helical receptor. It binds to N-formylated peptides produced by bacteria, and rarely by mitochondria.

8.2 Antigen Recognition Receptors

Macrophages express several receptors on their surface, which are able to recognize a large variety of bacterial or viral constituents (Table 5). The peculiarity of some of these surface receptors is that they can bind pathogen surfaces directly. These receptors are also known as pattern-recognition molecules, as discussed above. Receptors of the innate immune system mediate different functions. Several of the

Tab. 5 Antigen recognition receptors on macrophages.

Receptor	*Ligand(s)*
Mannose receptor (CD206)	Terminal mannose or fucose of glycoprotiens or lipids
Scavenger receptor (CD36)	Anionic polymers on microbial surfaces, apoptotic bodies
f-Met-Leu-Phe receptor	N-formylated peptides
TLR2	Peptidoglycans Lipopeptides
TLR3	dsRNA
TLR4/CD14	Endotoxin (LPS)
TLR4/CD91	Hsps
TLR5	Bacterial flagellin
TLR9	CpG oligonucleotides

known receptors are phagocytic receptors that stimulate ingestion of pathogens. One of these receptors is the mannose receptor (MR). The MR is also expressed on DCs, but not on monocytes or neutrophils. The MR is a C-type lectin that binds specific arrays of terminal mannose or fucose residues of glycoproteins and glycolipids, as they are found on the surface of many bacteria and some viruses, including the human immunodeficiency virus (HIV).

Mammalian equivalents contain terminal sialic acid or N-acetylgalactosamine, which is why the MR recognizes microbes and not host cells. Bacterial carbohydrates are also bound by the glucan receptor. Another receptor is the scavenger receptor (CD36). Originally, this receptor was found to bind to aberrant low-density lipoproteins (LDLs) that are unable to be taken up via the LDL receptor. Today it is known that CD36 is involved in removal of old red blood cells and in recognition and removal of pathogens.

Moreover, macrophages express several types of Fcγ receptors suitable for binding the Fc portion of IgG antibodies. During a humoral response, soluble IgG molecules coat the microbes and thereby promote phagocytosis by macrophages. Host proteins such as IgG that promote phagocytosis of microorganisms, such as bacteria, are called *opsonins*. Further opsonins are fragments of the complement factor C3 and plasma proteins, such as fibronectin, fibrinogen, C-reactive protein, or the mannose-binding lectin. They coat microbes early in the course of an infection before specific antibodies are available and bind to receptors, such as the integrins $\alpha_v\beta_3$ and Mac-1 (CD11b/CD18).

A third class of receptors that binds microbial components induces effector molecules that mediate initiation of an innate immune response. The best-defined activation pathway of this type is triggered through the family of Toll-like receptors. The name for these receptors reflects the fact that their extracellular regions are homologous to the protein Toll of the fruit fly Drosophila. In this invertebrate, Toll triggers the production of antifungal peptides in response to fungal infection. In mammals, a Toll-family protein called *Toll-like receptor 4*, or TLR-4, signals the presence of the gram-negative cell-wall component LPS, also named *endotoxin*. The polysaccharide moieties of LPS vary strongly between bacterial strains and are major antigens in inducing an adaptive immune response. The lipid moiety, by contrast, is conserved and is a good example of a molecular pattern recognized by the innate immune system.

The LPS recognition system of macrophages consists of 3 components: (1) a plasma protein, termed *LPS–binding protein* (LBP); (2) CD14, which binds LPS bound to LBP; and (3) TLR-4, the signal-transducing receptor. Circulating LPS is captured by LBP, whereupon the LPS-LBP protein binds to CD14. Upon dissociation of LBP, LPS-CD14 engages TLR-4 leading to activation of the macrophage. This is accomplished via a signal transduction pathway sharing structural homology with the type-I IL-1 receptor pathway. Both IL-1 and LPS stimulate activation of the transcription factor NF-κB, leading to cytokine secretion and activation of inflammation.

Another mammalian Toll-like receptor, TLR-2, signals the presence of another set of bacterial components that mainly include proteoglycans of gram-positive bacteria. TLR-2 and TLR-4 induce similar but distinct signals. Macrophages are also able to sense the intracellular presence of bacterial DNA. Bacterial DNA contains unmethylated cytidine–guanidine sequences, the so-called CpG nucleotides.

Unmethylated CpG nucleotides, organized in palindromic stretches are rather rare in mammalian DNA. If enough of these CpG sequences accumulate intracellularly, macrophages start secreting IFN-γ and IL-12. According to recent results, this response is mediated via TLR-9.

Two other receptors of the TLR family, which are functionally investigated are TLR-5 and TLR-3. TLR-5 was found to bind the bacterial motor protein flagellin, whereas TLR-3 is discussed to bind viral dsRNA. The functions of other proteins of the TLR family, which comprises 10 members, are currently being explored.

8.3 Macrophage Activation

Unactivated macrophages stand out for their high rate of phagocytosis and chemotactic movements and they proliferate. This is sufficient to cope with low numbers of pathogens in an antigen-independent way. However, in order to function as an APC and to gain high antimicrobial effectiveness, macrophages have to be activated. Such an activated macrophage can damage a broad spectrum of microbes and even certain tumor cells, but also healthy self-tissue. Therefore, macrophage activation must be tightly regulated. This regulation is achieved through the requirement of two coinciding signals. Signal 1 is provided by IFN-γ, signal 2 can be provided by different means, for example, LPS, engagement of CD40L, or cognate TCR (Fig. 7).

Activated $CD4^+$ T_{H1} cells can deliver both signals very efficiently: they secrete high doses of IFN-γ and express CD40L. Activated $CD8^+$ CTLs also secrete IFN-γ; however, recognition of MHC-antigenic peptide complexes by macrophages is not always sufficient to attain full activation of macrophages – the presence of low amounts of LPS or membrane TNF-α can compensate for the lack of CD40L on $CD8^+$ T cells.

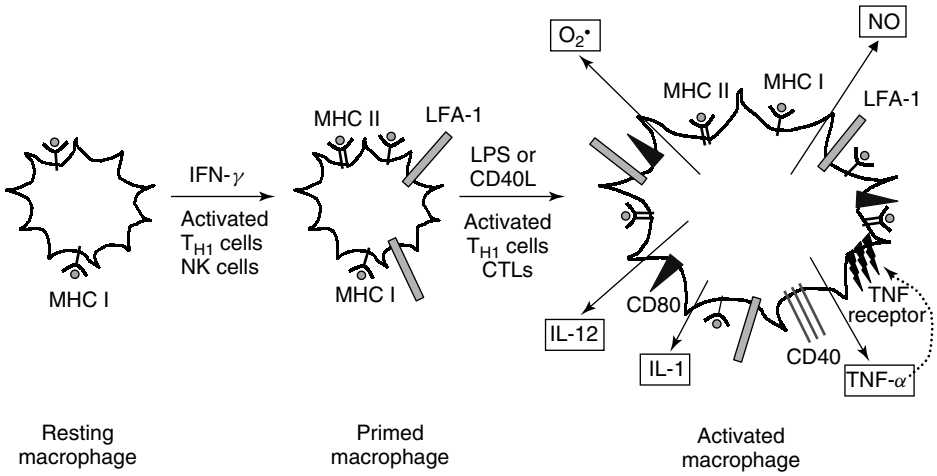

Fig. 7 The two-step model of macrophage activation. In the first step, resting macrophages are primed by IFN-γ secreted by activated T_{H1} or NK cells. Fully activated macrophages are generated in a second step upon encounter of CD40L or LPS. Activated macrophages express MHC class II molecules, costimulators, for example, CD80, CD40, and the TNF receptor. They secrete the cytokines IL-12, IL-1, and TNF-α and the radicals NO and superoxide ($O_2^{\bullet}$).

Another source of IFN-γ, which is rapidly available at the onset of an infection, is NK cells, thus supporting T_{H1}-mediated macrophage activation. T_{H2} cells counteract macrophage activation in that they secrete IL-10 but not IFN-γ. Macrophage activation by T_{H1} cells expressing CD40L and secreting IFN-γ is central to the host response to pathogens that proliferate in macrophage phagosomes, such as *Mycobacteria tuberculosis*, *Mycobacteria leprae* or *Leishmania* species. The same is true for vaccinia virus. Activated macrophages can clear internal microbes by overcoming the block in fusing phagosomes with lysosomes, so that lysis and degradation in phagolysosomes can occur. More importantly, activated macrophages produce the bactericidal nitrogen metabolite NO (see below).

By the late 1960s, the basis of acquired cellular immunity to facultative and obligate intracellular parasites was ascribed to activated macrophages. E. Metchnikoff wrote "The acquisition of immunity against microorganisms is therefore due not only to the change from negative to positive chemotaxis but also to the perfection of the phagocytic and digestive powers of the leukocytes – a general superactivity and adaptation of the phagocytic reaction is produced."

8.4 Immunological and Nonimmunological Effector Functions

8.4.1 Microbial Killing

T_{H1} cells activate infected macrophages through their TCR engaging MHC class II–antigenic complexes on the macrophage surface and the focal secretion of IFN-γ. The consequence is a series of events that converts the macrophage into a potent antimicrobial effector cell. An important intracellular event, which can be nicely observed by modern microscopy technologies, is the induced fusion of phagosomes with lysosomes, thereby exposing intracellular or recently ingested microbes to microbicidal lysosomal hydrolases leading to their destruction.

Other changes render macrophages more potent APCs and thereby help amplify an adaptive immune response: surface MHC class II, CD80, CD86, LFA-1, CD40, and TNF receptor are upregulated, thereby increasing the efficacy of macrophages in presenting antigen to resting $CD4^+$ T cells and the responsiveness to CD40L and TNF-α.

TNF-α synergizes with IFN-γ in inducing the enzyme inducible NO synthetase (iNOS), which produces the reactive nitrogen metabolite NO. NO together with oxygen radicals are secreted by activated macrophages leading to cell damage in the close neighborhood. Together with secreted proteases, NO and O_2 radicals are even able to attack large extracellular pathogens such as parasitic worms, which cannot be ingested, or intracellular pathogens that resist or survive phagolysosome fusion. The price to pay is that host tissue is destroyed as well by radicals and other toxic mediators.

Fully activated macrophages also secrete various types of cytokines, for example, TNF-α, IL-1, IL-6, and IL-12. IL-1 increases the access of effector T cell, TNF-α is an autocrine stimulus and increases the vascular permeability, IL-6 favors lymphocyte activation and IL-12 favors differentiation of $CD4^+$ T cells into T_{H1} cells and activates NK cells.

Besides priming macrophages through the focal secretion of IFN-γ, T_{H1} cells are very important in the recruitment of macrophages to sites of infection. This

is accomplished in three ways: (1) T_{H1} cells secrete the hematopoietic growth factors IL-3 and GM-CSF (granulocytes-macrophage-colony-stimulating factor), which stimulate generation of monocytes and neutrophils in the bone marrow; (2) T_{H1} cells at sites of infection secrete TNF-α and TNF-β which promote diapedesis of monocytes in endothelia; (3) T_{H1} cells in inflamed tissues secrete the chemokine MCP-1 (macrophage chemotactic protein), which attracts macrophages.

8.4.2 Tissue Remodeling

Macrophages, in particular activated ones, can secrete a number of proteins not directly related to their functions in innate or acquired immune responses but leading to local changes in the architecture of the tissue where macrophages are residing. Macrophages are the principal source of angiogenic factors, for example, vascular-endothelial growth factor (VEGF), factors that stimulate fibroblast proliferation, for example, platelet-derived growth factor (PDGF), and factors that regulate connective tissue biosynthesis, for example, transforming growth factor-β (TGF-β). Beyond that, unlike neutrophils, macrophages secrete proteases belonging to the matrix-metalloproteinases that degrade extracellular matrix proteins. At the same time, they activate fibroblasts to synthesize new matrix proteins. In settings of prolonged activation, macrophages even mediate tissue fibrosis.

8.5 Deactivated and Alternatively Activated Macrophages

In order to minimize local tissue damage and energy consumption, macrophage activation needs to be downregulated at a certain point of time. One way of achieving this is by T_{H1} cells regulating the half-life of their mRNA encoding IFN-γ. Activation of T_{H1} cells through engaging MHC class II–peptide complexes, CD80/CD86, and CD40 on the macrophage surface induces a new protein that promotes cytokine mRNA degradation, including IFN-γ mRNA. Another regulatory mechanism is the production of deactivating glucocorticoids and cytokines, such as TGF-β, IL-4, IL-10, and IL-13, especially by T_{H2} cells. Thus, the induction of differentiation of T_{H2} cells is a critical pathway for controlling the effector functions of activated macrophages.

More recently, however, IL-4 and glucocorticoids were found to induce increased expression of the MR and to enhance the capacity for endocytosis and antigen presentation of macrophages. This argues against mere deactivation and gave rise to the concept of alternative activation of macrophages. Alveolar and placental macrophages are typical examples. They express certain molecules selectively, such as the chemokine AMAC-1 (alternative macrophage activation-associated chemokine-1). AMAC-1 is related to MIP-1α, induced by classical macrophage activators, such as LPS, and inhibited by IL-4. Conversely, AMAC-1 is specifically induced by IL-4 and IL-10 and inhibited by IFN-γ. AMAC-1 is supposed to facilitate a downregulatory T_{H2} circuit in inflammatory reactions. Moreover, tumors secreting IL-10 and TGF-β may systemically and locally induce alternative macrophage activation. These macrophages may facilitate immune escape mechanisms, observed in malignant tumors, by secretion of growth and angiogenic factors supporting enhanced vascularization and nutrition of the tumor. More insight into the role of alternatively activated APCs is required.

9
B lymphocytes

B lymphocytes (short: B cells) can also serve as APCs, in particular, in the phase after a T-cell response has been initiated. In contrast to macrophages, B cells are known for their constitutive expression of MHC class II molecules. Furthermore, only B cells and some medullary thymic epithelial cells, but not other APCs, express the nonclassical MHC class II allele HLA-DO which is thought to regulate antigen processing in a B cell–specific manner. Similar to macrophages, B cells need an activation signal to express costimulatory molecules, thus, avoiding interaction with self-reactive T cells.

It has been known for a while that B cells are the key players in a humoral immune response, as they are the only cells of the immune system which can produce and secrete antibodies recognizing antigenic molecules. We will focus here on the capacity of B cells to function as APCs. Interestingly, it is still open as to how important B cells are in priming naive T cells in natural immune responses. This relates to the fact that B cells are uniquely adapted to bind and internalize mainly soluble molecules through their B-cell receptor (BCR), which is surface immunoglobulin (cf Fig. 2). However, during a bacterial or viral infection, particulate antigen is abundant but soluble antigen is rare. Therefore, it is not very likely that the limited number of B cells will detect soluble antigen that is only present at very low concentrations and that such an event is needed to prime a helper T cell. It is by far more likely that the main task of B cells is to present peptide antigens in the context of MHC class II molecules in order to receive a signal from activated T cells leading to their differentiation into antibody-secreting plasma cells.

9.1
Antigen-induced B-Cell Activation

The activation of B cells in an antigen-specific manner is initiated by the binding of antigen to the BCR. The BCR serves two key roles in B-cell activation: (1) antigen-mediated clustering of the BCR–antigen complexes initiates a signaling cascade; (2) BCR mediates endocytosis of BCR–antigen complexes into MIIC compartments where MHC class II molecules capture antigenic peptides to be presented to $CD4^+$ helper T cells.

Delivery of signals by the BCR starts upon clustering of at least two BCR complexes. *In vivo*, clustering is thought to occur by multivalent antigen. In resting B cells as well as in B cells that have undergone isotype switching, membrane molecules are associated with two other molecules, termed Igα and Igβ. Both of them are disulphide-linked heterodimers. The cytoplasmic domains of Igα and Igβ contain immunoreceptor tyrosine-based activation motifs (ITAMs), which are tyrosine enriched. Cross-linking of IgM or IgD molecules brings several ITAMs into closer proximity, thereby triggering subsequent signaling events. Initiation of signaling is accomplished via src family protein tyrosine kinases, such as Lyn, Fyn, or Blk, which are associated with the BCR and trans-phosphorylate ITAMs. Downstream signaling events ultimately activate transcription factors such as Fos, JunB, or NF-κB that induce the expression of genes whose products facilitate B-cell activation.

B-cell activation requires, in addition to antigen, second signals, which may be provided by complement proteins; for example, C3d binds to the type 2 complement–receptor CR2 on B cells (Fig. 8). Since C3d binds covalently to microbial antigens in the course of complement activation, antigen-C3d complexes can bridge the BCR and CR2. Binding of C3d to the B-cell complement receptor recruits CD19 and the tetraspanin CD81 into the complex. CR2-CD19-CD81 is often called the B cell coreceptor complex. Phosphorylation of the cytoplasmic tail of CD19 by the BCR-associated kinases leads to augmentation of the humoral immune response by 100- to 1000-fold. In summary, a proteolytic fragment of complement, which is induced by microbes, provides the second signal for B-cell activation. This is reminiscent of T-cell activation depending not only on signal 1 (TCR-MHC-peptide interaction) but also on costimulation (CD80/CD86-CD28 interaction).

9.2 Antigen Presentation Outside the Follicular Center

Within 1 to 2 days after antigen administration, B cells recognize antigen in the follicles of peripheral lymphoid organs, are activated, and begin to migrate out of the follicles toward the T-cell zones. The initial encounters between antigen-stimulated B and T cells occur at the interphase of the follicles and the T-cell zones (Fig. 9). In striking contrast to other APCs, B cells do not migrate into tissues where pathogens enter the body, but the antigens have to be transported into lymph nodes or to the spleen via the lymphatic vessels or blood stream to meet B cells.

9.2.1 B-cell Epitope versus T-cell Epitope

The three-dimensional molecular structure of an antigen that is recognized by the BCR of a B cell is termed the *B-cell epitope*, which is a conformational epitope.

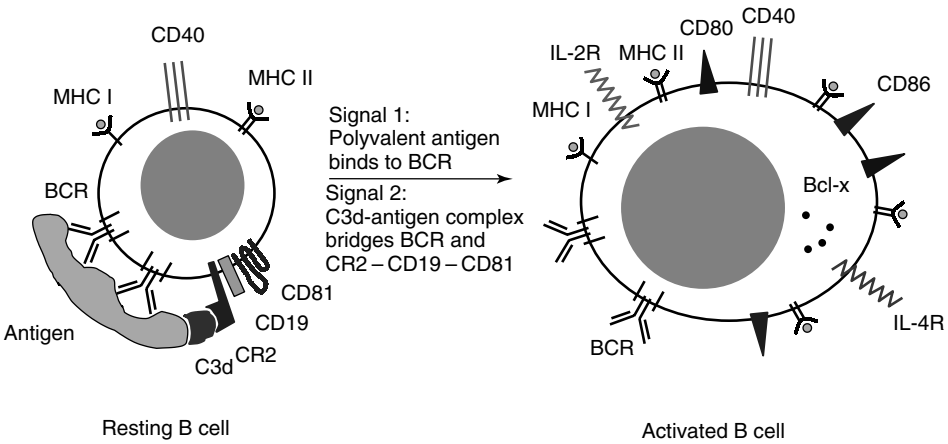

Fig. 8 Activation of B cells: resting B cells bind polyvalent antigen via the B-cell receptor (BCR) thereby generating signal1. The complement factor C3d bridges the antigen with another signaling complex consisting of the complement receptor CR2, CD19, and CD81, thereby generating signal 2. Activated B cells express costimulatory molecules, for example, CD80 and CD86, the IL-2 receptor (IL-2R), and the IL-4 receptor (IL-4R).

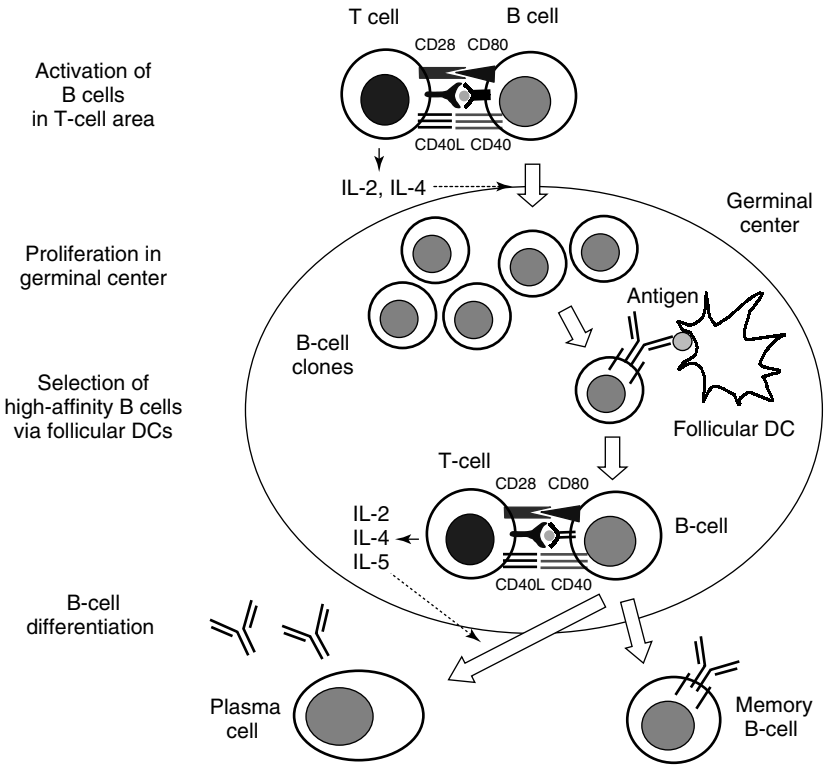

Fig. 9 T cell–B cell interactions outside and inside germinal centers: B cells encountering activated T cells in the T-cell areas of a lymph node are stimulated via cytokines to proliferate and form the germinal center. Binding to follicular DCs, which present native antigen, leads to selection of high-affinity B cells. The B cells that have survived reencounter activated T cells thereby receiving a differentiation signal. This gives rise to antibody-secreting plasma cells and memory B cells.

The peptide that is generated by proteolytic digestion of the antigen, bound and presented by MHC class II molecules, and recognized by a $CD4^+$ T cell is termed "*T-cell epitope*." It is a linear epitope.

In the majority of cases, B- and T-cell epitopes are distinct entities with different functions. This can be nicely illustrated with hapten–protein conjugates: hapten-specific B cells bind the hapten via the BCR, which mediates efficient internalization. This means that the hapten contains the B cell epitope. The hapten, however, cannot be bound by MHC class II molecules. This is why a carrier protein is necessary: the T-cell epitope to be presented to $CD4^+$ T cells is a peptide derived from the carrier protein. The requirement for MHC-associated presentation of the T-cell epitope for T-cell activation accounts for the MHC restriction of B cell–T cell interactions.

Which mechanisms prevent B cells that do not possess an antigen-specific BCR but are localized close to an antigen-specific B cell, from so-called *bystander activation*? There are several characteristics of the B cell–T cell interactions that counteract

activation of bystander B cells: (1) the first activation signal is dependent on an antigen-specific BCR; (2) binding of an antigen, endocytosis, processing and loading onto MHC class II molecules occurs at 10^4 to 10^6-fold lower antigen dose in B cells expressing an antigen-specific BCR than in other cells; (3) only B cells that remain in prolonged and tight contact with a T cell have access to cytokines secreted by T cells in a polarized fashion upon activation. This is accomplished by formation of the immunological synapse (cf. Sect. 7.3.).

9.2.2 CD40–CD40L Engagement

CD40 is a member of the TNF receptor family and constitutively expressed on the surface of B cells. Its ligand, CD40L, is only found on the surface of T cells upon seeing cognate antigenic peptide in the context of MHC class II molecules and costimulatory molecules CD80 and/or CD86. When these activated helper T cells bind antigen-presenting B cells, CD40–CD40L interactions lead to CD40 oligomerization. This oligomerization initiates enzyme cascades finally leading to the activation and nuclear translocation of transcription factors, including NF-κB and AP-1. This pathway has already been discussed in the context of T cell–mediated macrophage activation; hence, it is a general mechanism for the stimulation of target cells by helper T cells.

The importance of the CD40–CD40L interaction in humoral immunity is underscored by the observations that CD40 or CD40L gene knockout mice and humans with mutations in the CD40L gene exhibit profound defects in affinity maturation of immunoglobulin and memory B-cell generation. Interestingly, a transforming protein of Epstein–Barr Virus (EBV), which infects human B cells, utilizes the same signaling pathway as CD40, with the consequence that EBV-transformed B cells proliferate rather rapidly, leading to lymphomas.

Three helper T-cell derived cytokines, IL-2, IL-4, and IL-5, contribute to proliferation of activated B cells (Fig. 9). Besides CD40-mediated signals, it is again cytokines, mainly IL-2, IL-4, and IL-6, that stimulate antibody synthesis, the production of secreted Ig and switching from IgM to the IgG, IgA, or IgE isotype. There is a clear preference of some cytokines to induce secretion of particular Ig isotypes, for example, IFN-γ promotes secretion of IgG2a, IL-4 favors IgG1, and IgE ad IL-5/TGF-β favor IgA production.

Ig-secreting B cells are found in the red pulp of the spleen, the medulla of the lymph nodes, and the bone marrow. Many of the antibody-secreting B cells change into plasma cells, which are specialized in producing and secreting soluble antibody.

9.3 Antigen Presentation in the Germinal Center

Within 4 to 7 days after antigen exposure, some of the activated B cells migrate back toward the center of the follicle and begin to proliferate rapidly, thereby forming the germinal center. The B cells in the germinal center are named *centroblasts* and *centrocytes*. They have a doubling time of 6 to 12 h, so that 1 B cell gives rise to a clone of about 5000 centroblasts in 5 days. It was estimated that on average, three B-cell clones colonize each follicle after a single immunization. In particular, CD40–CD40L interactions and presentation of cognate peptide antigens on MHC class II molecules are required to maintain proliferation of centroblasts and to allow further differentiation.

9.3.1 B Cell/Follicular DC Contacts

Some of the mutations generated during somatic mutations in immunoglobulin genes are likely to be useful because antibodies with higher affinity are generated. However, the majority of the mutations may lead to a decline or even loss of antigen binding or to recognition of self-antigen. Therefore, the next step in the process of affinity maturation is the selection of the useful, high-affinity B cells that do not react with self.

To this end, follicular dendritic cells (FDCs) are required to engage hypermutated B cells. FDCs have long cytoplasmic processes that form a network around which germinal centers are formed (Fig. 9). FDCs do not express MHC class II molecules, and hence, are not related to classical DCs, but they express several complement receptors, Fc receptors, and CD40L. These receptors bind and display intact antigen that are decorated with Ig or complement factors. Signals generated by antigen binding – mediated by FDCs – to surface Ig on the B cell block a default cell death pathway by inducing antiapoptotic protein of the Bcl family.

With increasing numbers of antigen-specific antibodies being available, more and more of the antigen is captured, and thus, the concentration of available antigen in the germinal center decreases. Therefore, these B cells that are still able to capture antigen have to have a high affinity for the antigen – and only they will survive. The survival of the respective B cells involves uptake and processing of antigen hold on FDCs, and its presentation to T cells via MHC class II molecules (Fig. 9). This event will lead to T-cell activation – the CD40–CD40L interaction conveys long-term survival to the respective centrocyte. The net result of this selection process is a population of B cells producing antibodies with significantly higher affinities for antigen than the antibodies produced by the same clones of B cells earlier in the immune response.

Some antigen-activated B cells acquire the ability to survive for long periods of time. They are termed *memory B cells* capable of mounting rapid responses to subsequent infections. It is possible that memory cells are continually generated and maintained by antigenic stimulation, facilitated by the help of FDCs. Memory B cells typically bear high-affinity Ig. The production of large quantities of high-affinity antibodies is strongly accelerated after secondary exposures to antigen. This can be attributed to the activation of B cells in germinal centers and the rapid formation of immune complexes presented by FDCs and processed by memory B cells in order to contact cognate T helper cells.

9.3.2 HLA-DO

HLA-DO is an MHC class II molecule that is unable to bind peptide but serves as a regulator of the peptide editor and chaperone HLA-DM. HLA-DO is expressed in B cells, but not in other APCs. In further contrast to the classical MHC class II molecules and to HLA-DM, HLA-DO expression is initiated only after B-cell development is complete, that is, when B cells start becoming capable of interacting successfully with T cells.

HLA-DO is tightly bound to HLA-DM and is rapidly degraded in the absence of HLA-DM. HLA-DM–HLA-DO complexes are poorly active in removal of the CLIP peptide, especially at moderate pH found in early and late endosomes, suggesting that HLA-DO is a negative regulator of antigen presentation. However, at the

same time, HLA-DO acts as a cochaperone of HLA-DM, which is particularly relevant at the low pH found in lysosomal MIICs of B cells. Thus, by limiting the catalytic function of HLA-DM in all but the most acidic MIICs, HLA-DO appears to selectively promote loading and presentation of antigenic peptides derived from proteins internalized through the BCR. The rationale is that very low pH, a high redox potential, and a high abundance of proteases, typical characteristics of lysosomal MIICs, are required for efficient processing of antigens tightly bound to BCRs.

Strikingly, the capacity of B cells to present antigen to helper T cells is controlled via differential expression of HLA-DO in quiescent B cells as compared to activated B cells in germinal centers. In peripheral blood B cells, 50 to 100% of HLA-DM is associated to HLA-DO. This leads to inefficient CLIP removal, and hence to high surface levels of MHC class II-CLIP complexes and to a reduced capacity to process self- or foreign antigen. The conclusion is that due to the comparably high abundance of HLA-DO, peripheral B cells are reduced in their potential to present foreign antigen. The role of class II-CLIP complexes, as typical representatives of self, in peripheral tolerance induction with regard to self-reactive T cells has to be elucidated.

In germinal centers, however, HLA-DO is markedly downregulated so that CLIP is efficiently released from MHC class II molecules and antigenic peptides derived from internalized BCR–antigen complexes have access to the binding cleft of class II molecules. As 20 to 30% of HLA-DM is still associated to HLA-DO, peptide receptive ''empty'' class II molecules are chaperoned by HLA-DM–HLA-DO complexes until BCR-mediated uptake of foreign antigen occurs. In summary, regulated HLA-DO expression allows optimization of antigen processing and presentation to helper T cells in germinal centers during the development of humoral immune responses.

10 Dendritic Cells (DCs)

Dendritic cells (DCs) represent a highly heterogeneous population of APCs, at the same time being the most potent APCs. They are bone marrow–derived and reside in most peripheral tissues as sentinels of the adaptive immune system. As DCs, similar to cells of the innate immune system, express various types of TLRs that mediate recognition of microbial danger motifs, DCs are also most critical in bridging innate and adaptive immunity.

DCs are specialized for the uptake, transport, processing, and presentation of antigens to T cells. Any encounter with microbial products or tissue damage initiates the migration of DCs out of peripheral tissues to lymph nodes and their differentiation into the mature state. Mature DCs express strongly upregulated levels of MHC and costimulatory molecules so that, in lymph nodes, DCs can trigger an immune response by any T cell with a receptor that is specific for MHC-foreign peptide complexes on the DC surface. Since subsets of DCs are constantly carrying self-antigens into lymph nodes without receiving a maturation stimulus, DCs are thought to play a major role in the maintenance of peripheral tolerance against self as well.

10.1 DC Subsets

Phagocytic cells carrying numerous dendrites and expressing considerable amounts of MHC and costimulatory molecules in their unactivated state are found in distinct microenvironments of our body, for example, in peripheral tissues, in lymph nodes, and in the thymus. In addition, DCs do not only interact with T cells, but also with B cells and with NK cells. These aspects render it most likely that the various and often opposing functions ascribed to DCs can only be performed by different sets of DCs. According to the functional plasticity model, only a single DC lineage (hematopoietic precursor, DC precursor, immature DC, mature DC) exists and local environmental factors cause functional diversity (Fig. 10). According to the specialized lineage model, however, specialized DC subtypes are the product of entirely separate developmental lineages, with DC precursors being already functionally committed. It appears that in reality, we are facing a complicated mixture of both models.

10.1.1 Myeloid Versus Lymphoid DCs

Distinct DC subtypes were initially more evident among mouse DCs than among human DCs because of the availability of

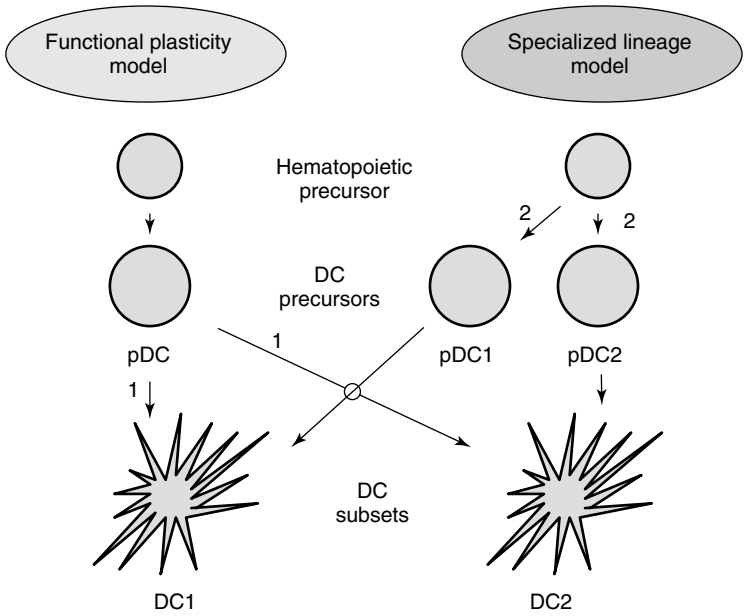

Fig. 10 Generation of functionally distinct DC subsets. According to the functional plasticity model, all DCs belong to a single hematopoietic lineage, the subtypes DC1 and DC2 being generated by local environmental factors in the periphery (1). The specialized lineage model proposes that DC subsets originate from early divergences in the development, triggered by the microenvironment of the bone marrow (2), giving rise to distinct precursors, pDC1 and pDC2. Subsequently, pDC1 and pDC2 function as the precursors of the DC1 and DC2 subsets respectively.

different murine lymphoid tissues and the expression of distinct markers not present on human DCs. Hence, there was evidence that the $CD8^+$ DCs of the thymus shared early steps of development with T cells. They were thought to derive from lymphoid-restricted precursors and were named *lymphoid DCs*. All other DCs being $CD8^-$ were thought to originate from myeloid-restricted precursors; they were called *myeloid DCs*. In the meantime, when myeloid- and lymphoid-restricted precursors were isolated from bone marrow, it became evident that each precursor could produce all the mature splenic and thymic DC subtypes. Besides CD8 and CD4, the integrin α_M chain (CD11b), the lectin DEC205 (CD205) and the integrin α_X chain (CD11c) are used as surface markers to distinguish murine DC subtypes. Currently, the terms *myeloid* and *plasmacytoid* (Table 6) are used to distinguish DC lineages in both mouse and man.

10.1.2 Human DC Subtypes

In contrast to the situation in mice, only blood and bone marrow can be used as an *ex vivo* source of human DCs. Human blood DCs are highly heterogeneous in their marker expression, with many markers reflecting differences in the maturation or activation state rather than separate lineages. A comparison to mouse subtypes is difficult, since human DCs lack expression of CD8. Only human thymic DCs make a strong case for subset segregation, similar to that in mouse: most human thymic DCs are $CD11c^+$ $CD11b^-$ and lack myeloid markers, and so resemble murine thymic $CD8^+$ DCs.

As yet, most insight into DC subsets has come from studies of their development in culture from precursors. Essentially three distinct precursor types have been used: $CD34^+$ bone marrow–derived precursors, blood monocytes, and plasmacytoid cells (Table 7).

$CD34^+$ precursor pathway The earliest precursors used are $CD34^+$ and derived from bone marrow or umbilical-cord blood. Liquid culture with granulocyte-macrophage colony-stimulating factor (GM-CSF) and TNF-α leads to two

IL-3 receptor	−	−	++
CD4	+	+	+++

apparently separate pathways of DC development, which can be distinguished by the expression of a skin-homing factor, known as *cutaneous lymphocyte-associated antigen* (CLA).

One pathway (via CD34$^+$/CLA$^+$ intermediates), depending on TGF-β, leads to DCs resembling Langerhans cells: they express the Langerhans cell–associated antigens Langerin and E-cadherin, CD11c, CD1a, and have Birbeck granules, characteristic structures known from electron microscopy studies of Langerhans epidermal DCs (Table 7).

The second pathway (via CD34$^+$/CLA$^-$, CD14$^+$ intermediates, which resemble blood monocytes) produces DCs reminiscent of intestinal DCs (Table 7). They lack Langerin and E-cadherin, but express the tetraspanin CD9, the coagulation factor XIIIa and CD68.

CD14$^+$ monocyte pathway Peripheral blood monocytes are the most commonly used precursors for generating human DCs in culture. CD14$^+$ monocytes differentiate into DCs (termed DC1) in the presence of GM-CSF and IL-4. In the presence of M-CSF, macrophages are generated. The monocyte-to-DC differentiation can also be accomplished by seeding monocytes onto a layer of endothelial cells over a collagen matrix, mimicking the entry of monocytes into tissues. Most of the monocytes that have migrated into the collagen matrix remain there and become macrophages. A subset of them, however, migrate back through the endothelial barrier and become DCs (Table 7).

Plasmacytoid cell pathway Human plasmacytoid cells, termed DC2, were found by their plasma cell–like morphology and their unique surface phenotype: they are strongly positive for the IL-3 receptor, but negative for CD11c and for myeloid mineage markers (Table 7). Strikingly, they produce mRNA for germ-line Igκ and pre-T-cell receptor α. Plasmacytoid cells are found in blood and many lymphoid tissues. They respond to viral and microbial stimuli by producing IFN-α and IFN-β.

10.2 Antigen Uptake Mechanisms

Tissue DCs capture pathogens, infected cells, dead cells, or their derived products, and also soluble material to use for antigen processing and presentation. Importantly,

binding and uptake of certain pathogen-derived components are in many cases linked to DC maturation. During DC maturation, they downregulate their endocytic capacity. The consequence is that antigen uptake is no longer possible during migration to and in the lymph nodes, but only in peripheral organs. Down-modulation of endocytosis is achieved in at least two ways: (1) a decrease in surface expression of several antigen-binding receptors; (2) inactivation of the GTPases cdc42 and rac1 widely abolishes macropinocytosis and phagocytosis.

10.2.1 Macropinocytosis Versus Phagocytosis

Macropinocytosis is a cytoskeleton-dependent type of fluid-phase endocytosis that certain growth factors can induce in macrophages. In immature DCs, however, macropinocytosis is a constitutive phenomenon. It allows DCs to sample large amounts of extracellular fluid in short periods of time. This is the nonspecific way of DCs to search for antigenic material. Antigens that have been captured by macropinocytosis have access to MIICs and hence can be loaded onto MHC class II or CD1 molecules.

Phagocytosis is initiated by the engagement of specific surface receptors; hence, it is to a certain extent antigen-specific. Immature DCs phagocytose whole bacteria, irrespective of whether they are gram-positive or gram-negative, but also yeast cells and hyphae. As part of the GALT, interstitial DCs penetrate tight junctions so that their dendrites have access to bacteria in the gut lumen.

Immature DCs also internalize cell debris from cells that have undergone cell death by apoptosis or necrosis. Human monocyte-derived DCs take up apoptotic and necrotic bodies derived from B or T cells, virus-infected apoptotic monocytes, or tumor cells, including melanoma cells or various carcinoma cells. Moreover, DCs have been shown to transport apoptotic intestinal epithelial cells to T-cell areas of mesenteric lymph nodes in rats. Phagocytosis of apoptotic bodies mainly occurs through a complex including the scavenger receptor CD36 and the integrins $\alpha_V\beta_5$ and $\alpha_V\beta_3$. The receptors needed for phagocytosis of necrotic cells are less well defined.

10.2.2 Receptors for Endocytosis

Receptors for the F_c portion of immunoglobulin belong to the prominent molecules on the DC surface: human monocyte-derived DCs express mainly FcγRII and FcαR, LCs express FcγRI and FcεRI, whereas blood DCs are positive for FcγRII and FcγRI. Recently, a novel member of the Ig superfamily, named Ig-like transcript (ILT)-3 was found to facilitate antigen processing in DCs, but also in monocytes and macrophages.

In contrast to macrophages, immature DCs express only the complement receptors CR3 and CR4, but not CR1 or CR2. Similar to macrophages, immature monocyte-derived DCs, blood DCs, and interstitial DCs of the dermis display high levels of the MR. The MR not only allows DCs to endocytose a large variety of bacterial and yeast antigens, but also desialylated immunoglobulin. Strikingly, LCs do not express the MR, but Langerin (CD207), which is also a lectin with mannose specificity. Unlike the MR, CD207 induces the formation of Birbeck granules. Finally, DCs are also very potent in binding and taking up Hsps, such as hsp70 and gp96. Recently, CD91, known as the α2–macroglobulin receptor, and CD40 were described to mediate endocytosis of Hsps of the Hsp70 and Hsp90

protein family. These findings are intriguing, as endogenous as well as foreign Hsps are discussed to mediate maturation of DCs. In particular, the activatory capacity of necrotic cells has been ascribed to Hsps

10.2.3 The Adhesion Receptor DC-SIGN

DC-SIGN (DC-specific ICAM-3-Grabbing Nonintegrin), also termed CD209, is a mannose-binding C-type lectin that is strongly and selectively expressed on DCs, irrespective of whether they are immature or mature.

DC-SIGN recognizes with high affinity the adhesion molecule ICAM-2 on vascular and lymphoid endothelia. ICAM-2 serves as a rolling counterreceptor, thereby enabling DC-SIGN$^+$ DCs to tether to and roll along endothelia. This is a prerequisite for trans-endothelial migration into peripheral tissues and secondary lymphoid organs. Thus, one function of DC-SIGN is to function as a DC-specific rolling receptor.

Upon reaching T cell–rich areas in secondary lymphoid organs, DC-SIGN mediates initiation of T cell–dependent immune responses: it enables transient DC–T-cell interactions through binding to ICAM-3, which is expressed on the surface of naive T cells. In contrast, DC-SIGN does not bind to the principal ligand of LFA-1, ICAM-1.

Finally, DC-SIGN functions as an HIV-1 trans-receptor important in the dissemination of HIV-1. HIV-1 is captured on DCs present in the periphery by DC-SIGN, which binds to the HIV-1 coat protein gp120. Thus, HIV-1 is transported by DCs that migrate into lymphoid tissues where DC-SIGN-associated HIV-1 efficiently infects target CD4$^+$ T cells.

10.3 Maturation of DCs

The various subtypes of human DCs described above vary considerably with regard to the expression of marker proteins and their behavior in the immature state. However, as soon as they are subjected to inflammatory stimuli, they share a common program, termed maturation, which transforms immature into mature DCs that are highly efficient in priming and activating T cells. They are by far more potent than activated macrophages or B cells in initiating a cellular immune response. This is mainly due to the fact that key proteins, for example, MHC molecules, costimulators, and accessory molecules, are much more abundant on mature DCs than on stimulated macrophages or B cells.

10.3.1 Maturation Stimuli

Immature DCs respond to two types of maturation stimuli: (1) direct recognition of pathogens via TLRs and other PPRs; and (2) inflammatory cytokines and other exogenous or endogenous mediators that are secreted during an infection or in other acute alarm situations (Fig. 11). In detail, DCs can recognize bacterial peptidoglycans, lipopeptides, and mycoplasma lipoproteins via TLR2, LPS via TLR4, viral dsRNA via TLR3 and certain DNA oligonucleotides via TLR9. It should be emphasized that TLR2 is not present on the cell surface, but specifically recruited to yeast-containing phagosomes. Likewise, TLR4 is not compulsory for internalization of LPS-carrying bacteria. This suggests that TLRs are involved in discrimination of microbes and not necessarily in their uptake. Apart from that, DCs have receptors in order to sense infections and

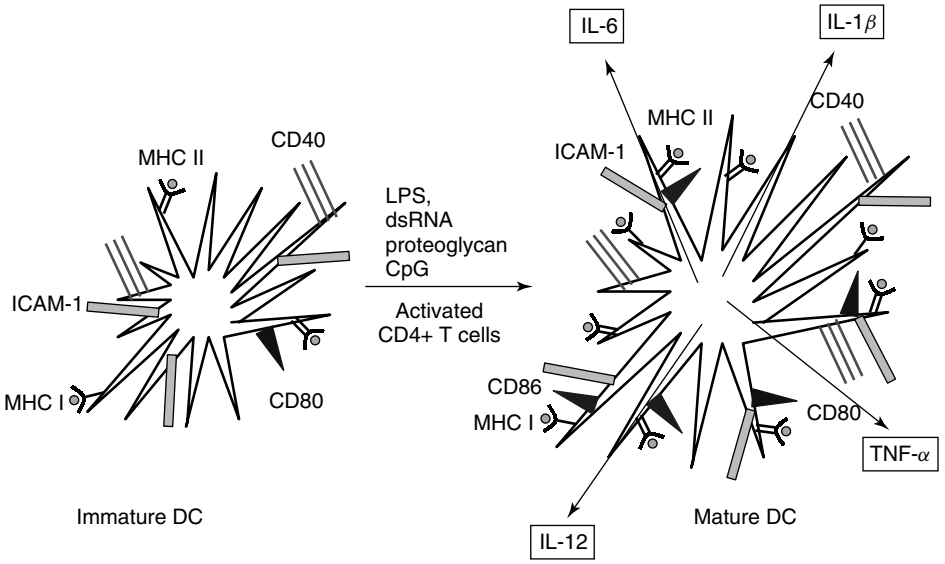

Fig. 11 Maturation of dendritic cells (DCs). Several microbial signals, including LPS, dsRNA, proteoglycan, and CpG, or the encounter of activated T helper cells induces the mature phenotype. Mature DCs strongly upregulate MHC, costimulatory and adhesion molecules and secrete the proinflammatory cytokines IL-12, IL-6, IL-1β, and TNF-α.

danger indirectly, via binding of TNF-α, IL-1β, or PGE_2, whose secretion is triggered by pathogens.

Moreover, whole viruses or bacteria decorated with immunoglobulins induce DC maturation via binding to FcR, including FcγRI, FcγRIII, and FcγR. Even more importantly, activated $CD4^+$ T cells provide a strong stimulus via CD40L that triggers CD40 of DCs. This signal appears to be essential for conditioning DCs in such a way that they are able to fully activate certain types of $CD8^+$ CTLs.

There is accumulating evidence that cell death gives rise to signals that render DC mature, as well. In particular, necrosis induces DC maturation, however, the mediators of this activation are still unknown. Apoptotic cells, at least after heat stress, are also capable of stimulating immature DCs. Nucleotides, such as ATP and UTP, and Hsps, including gp96, Hsp90, and Hsc70 are liberated extensively in the course of necrosis and have been proposed to function as danger signals being able to trigger DC differentiation. However, contaminations with LPS have been implicated in this context, so that it is doubtful, as yet, whether Hsps per se or Hsp-LPS complexes have induced DC maturation. Moreover, Hsp60 and Hsc70 have been described to activate macrophages through a CD14/TLR4 complex, but receptors on DCs are not characterized, yet.

10.3.2 The Danger Hypothesis

The model of self–nonself discrimination foresees that the baseline state of the immune system is "OFF." To initiate a cellular immune response, the key players, namely, APCs and T cells have to be activated. T cells get activated by the encounter of mature APCs. Such mature

APCs provide signal 1 via MHC-peptide complexes engaging TCRs. Since APCs appear to be unable to distinguish self-peptide from foreign peptide and since self-reactive T cells do exist in our body, the safe guard of the self–nonself discrimination model is signal 2. Signal 2 is only provided via costimulators of APCs that have recognized patterns of nonself molecules found only on evolutionary distinct organisms, such as bacteria or viruses. This is thought to be accomplished via PRRs, for example, TLRs. However, even Janeway, who pioneered the idea of pattern recognition serving for costimulation, pointed out that PRRs cannot explain autoimmunity or immune responses to tumors or transplants. Moreover, it is still open how the immune system deals with a changing self. The self–nonself discrimination model, for example, fails to give us a clue why vertebrates do not attack themselves at puberty and why females do not reject their own newly lactating breasts when they begin to produce milk proteins that were not part of self until that time.

The danger model pioneered by Matzinger gives an answer to these questions. This model is based on the hypothesis that the ultimate controlling signals are endogenous, not exogenous. They are the alarm signals that emanate from stressed or injured tissues (Fig. 12). Hence, cells of normal bodily tissue, when distressed, send signals that are called *danger signals*, which serve to activate local APCs. Healthy cells, in fact, may send calming signals to local APCs, whereas cells that are damaged or die by necrosis should favor maturation of APCs. In contrast, cells that die by apoptosis, a process of normal programmed cell death, should merely send signals that may favor phagocytosis but should not induce the expression of costimulatory molecules. This view is consistent with findings where necrotic cells do induce maturation of DCs, but not apoptotic cells. This correlates with the liberation of Hsps from necrotic but not apoptotic cells. Strikingly, apoptotic cells that have undergone heat stress were also able to activate DCs. As yet, Hsps are the only candidate for endogenous mediators of danger.

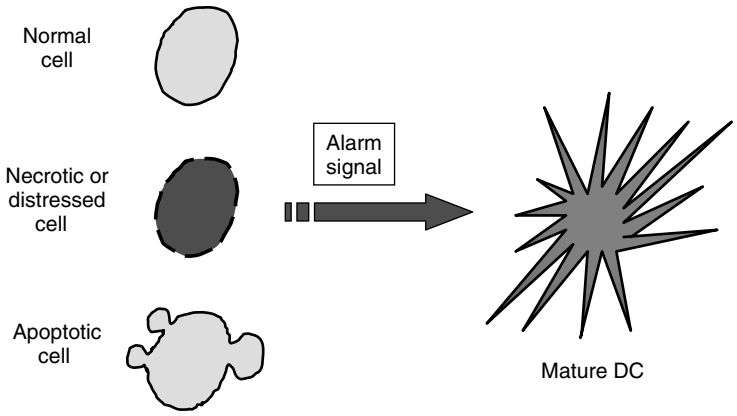

Fig. 12 The danger model DCs receive an alarm signal from injured, distressed, or necrotic cells leading to their maturation. This is not the case with normal cells or in cells dying by apoptosis.

10.4 Antigen Processing and Presentation

10.4.1 Classical and Cross-presentation via MHC Class I

Like other APCs and other nucleated cells, DCs present self- or virus-derived endogenous antigens to $CD8^+$ CTLs in an MHC class I–restricted manner. In contrast to other cells, DCs express low levels of the immunoproteasome already in the immature state and upregulate it upon maturation. Moreover, the abundance of MHC class I–peptide complexes increases during maturation. However, in contrast to the MHC class II pathway, mature DCs still synthesize and replace surface MHC class I molecules in their mature state. This finding raises the question, whether DCs that have captured a class I–restricted antigen in peripheral tissues, are the same DCs that will present this antigen to $CD8^+$ T cells in secondary lymphoid organs. Alternatively, DCs may capture antigens in the lymph node. In this case, DCs should be able to take up exogenous antigen and transfer it onto MHC class I molecules. This nonclassical mechanism had already been proposed by Bevan and colleagues: they showed that priming of CTL responses *in vivo* can occur after presentation of exogenous antigens by class I MHC molecules. These phenomena were referred to as *cross-presentation* of antigen and *cross-priming* of $CD8^+$ T cells.

In the meantime, cross-presentation has been shown to be a major pathway utilized by DCs in the context of various sources of exogenous antigens. Physiologically, phagocytosis appears to be a major route for antigen uptake and cross-presentation, as FcR-mediated uptake of immune complexes or opsonized dead cells promotes cross-priming. Furthermore, phagocytosis of bacteria, bacteria-derived antigens, and apoptotic cells results in cross-presentation of bacterial antigens and the same has been observed for viral and tumor antigens. Likewise, peptides bound to Hsps, including gp96, Hsp90, Hsp60, and Hsc70, are cross-presented by mature DCs.

Two pathways for cross-presentation were reported: the first foresees peptide loading in the endocytic system, and hence is TAP- and proteasome-independent. Recycling MHC class I molecules are, indeed, found in endosomes of immature DCs, where low pH is supposed to favor exchange of prebound peptide for exogenous peptide. The second pathway is TAP-dependent and was reported in DCs in several experimental settings. This pathway foresees the existence of a membrane transport system linking the lumen of endosomes and the cytosol. Other cells, for example, thymic epithelia cells or liver sinusoidal epithelial cells, are also able to present soluble exogenous antigen in a TAP-dependent fashion, albeit less efficiently than DCs.

As an alternative to explain cross-presentation, one could envisage that ER compartments fuse with nascent endosomal membranes before endosomes separate from the plasma membrane, as most recently shown for macrophages. This would allow loading of exogenous antigens onto MHC class I molecules in the ER without the need for a specialized transporter in the endosomal membrane. Physiologically, this mechanism could serve to feed the plasma membrane with phospholipids from the ER to compensate the loss of membranes due to endocytosis.

10.4.2 MHC Class II–restricted Antigen Presentation

The cell surface display of MHC class II–peptide complexes is tightly regulated

during the life cycle of DCs. An immature DC exposes around 10^6 MHC class II molecules on the surface. This is already more than activated B cells or macrophages can ever express, however, 5 to 10 times less than in mature DCs. Several reasons account for that: the efficiency of major proteases involved in antigen degradation in immature DCs, for example, cathepsins B and S, is low. This may be due to comparably high levels of endogenous protease inhibitors such as cystatin C and the Ii splice variant Iip41. Another aspect is that not all endosomes or phagosomes may have access to MIICs, where MHC class II molecules are loaded with peptide. Finally, MHC class II–peptide complexes have a short half-life ($\leq$10 h) in immature DCs, since they are constantly internalized and transported to recycling endosomes, where peptide exchange occurs, or is degraded in lysosomes. Nevertheless, it should be pointed out that immature DCs are able to present self- and foreign antigen peptides to $CD4^+$ T cells. According to current concepts, this process serves mainly to tolerize T cells against self-antigens.

Inflammatory signals activate a program leading to profound changes in antigen processing for class II molecules. MHC class II biosynthesis is transiently upregulated, the activity of processing proteases increases accompanied by their relocalization into MIICs and recycling of class II molecules ceases widely. Following peptide loading in MIICs, subsets of class II molecules associate with the costimulator CD86 and the tetraspanins CD82 and CD63, thereby becoming a part of multimeric clusters that are transported to the cell surface. At the cell surface, class II peptide complexes remain organized in a multimerized fashion, mainly associated to tetraspanins. The tetraspan microdomains, which are strongly upregulated in mature DCs, not only concentrate MHC-peptides complexes but also enrich MHC class II molecules loaded with particular peptide. This increases the local avidity to T cells and, hence, increases the efficacy of T-cell activation. This is further supported by the fact that the mature DCs no longer endocytose class II molecules so that the latter become rather long-lived. After 10 to 20 h of maturation, no further class II molecules are synthesized and the activity of HLA-DM is strongly downregulated so that peptide loading ceases. Thus, mature DCs that have reached the T-cell areas of lymph nodes mainly present those peptide antigens to $CD4^+$ T cells that they have captured before or during induction of maturation in peripheral tissues.

10.5 T Cell Priming and Polarization

10.5.1 Priming of $CD8^+$ and $CD4^+$ T Cells

Several lines of evidence support the concept that DCs are the principal APCs for T-cell priming. This is based on *in vitro* observations, where DCs were compared to other APCs for priming alloreactive, naive T cells or the expansion of naive precursors from polyclonal populations. Furthermore, injection of antigen-loaded DCs induces potent $CD4^+$ and $CD8^+$ T-cell primary responses. By immunofluorescence on lymph node sections, interactions of DCs and T cells could be directly visualized. Beyond that, DCs break peripheral tolerance against transplantation antigens and tumor antigens. Moreover, the exclusive expression of MHC class II molecules in DCs was sufficient for the establishment of central tolerance through Vβ-specific deletion of T cells by a superantigen presented by DCs in the thymus medulla.

The outstanding T-cell priming capacity of mature DCs is mainly due to the enhanced surface levels of costimulatory CD80 and CD86 and adhesion molecules, but also connected to a rapid relocalization of antigen-bearing DCs to the T-cell zones of secondary lymphoid organs. The *in vivo* relevance of DC maturation in T-cell priming is particularly evident in the case of $CD8^+$ T cells. Although there are examples of direct priming of CTLs by DCs without the involvement of $CD4^+$ T cells, numerous cases have been described, where $CD8^+$ naive T cells are dependent on $CD4^+$ T-cell help. It was found that CD40 ligation on DCs by CD40L on $CD4^+$ T cells was necessary and sufficient to confer to DCs the ability to prime CTLs. At the same time, DCs are rendered mature (Fig. 13).

This mechanism allows a temporal dissociation of interactions between DCs, $CD4^+$ helper T cells, and $CD8^+$ CTLs: once licensed by $CD4^+$ T cells, mature DCs are competent to prime $CD8^+$ T cells. This model, also known as the *license-to-kill model* bypasses the requirement of a tricellular interaction of DCs, activated helper T cells and naive CTLs in lymph nodes, which is rather unlikely to occur. Apart from helper T cells, pathogen-derived products, such as LPS, viruses or apoptotic bodies carrying CD40L have been shown to deliver licensing signals to DCs.

10.5.2 T Helper Cell Polarization

In the most recent literature, the issue of T-helper cell polarization by DCs has received considerable attention. Various pathways of regulation are operative. Immature DCs *per se* favor T_{H2} polarization, but they can be reinstructed by the characteristics of the antigen or its accompanying adjuvant to induce a T_{H1}, T_{H2}, or an undifferentiated T_{H0} response (Table 8).

Microbe-derived pattern molecules, such as LPS or CpG oligonucleotides, drive T_{H1} polarization by induction of IL-12, IL-6, and IL-1β secretion through binding to TLRs. However, microbial products often need additional host-derived microenvironmental instruction to

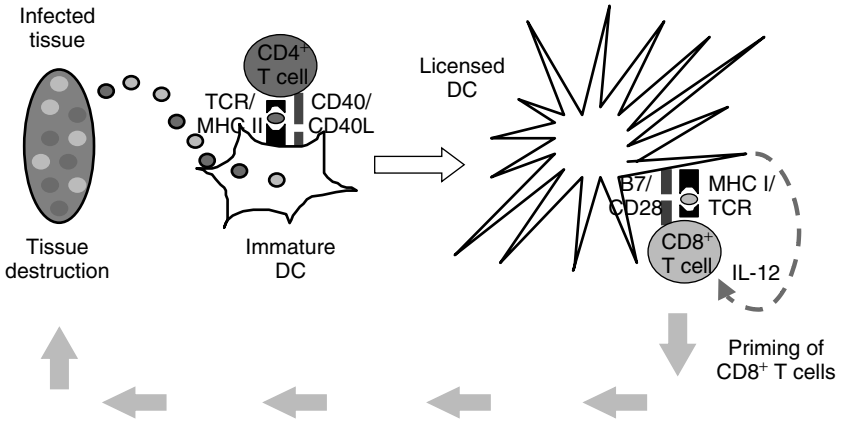

Fig. 13 The license-to-kill model of DCs. Immature DCs that encounter activated $CD4^+$ Thelper cells receive a signal through CD40/CD40L engagement. DCs that have received this signal are able to render cytotoxic $CD8^+$ T cells highly potent in killing infected target tissues. Thus, DCs conditioned by Thelper cells bear the license to kill.

Tab. 8 T helper cell polarization mediated by DCs.

	T_{H1} *bias*	T_{H2} *bias*
Antigen dose	High	Low
Type of antigen	*Candida albicans yeast* Toxoplasma antigen	*Candida albicans hyphae* Allergens
Adjuvants	CpG oligonucleotides LPS	PGE_2 Cholera toxin
MHC-TcR interaction	High affinity Short interaction	Low affinity Sustained interaction
Stimulator/responser ratio	High	Low
Costimulators	ICAM-1 CD40	OX40-L ICOS-L
DC state	Mature	Immature
DC type	$CD1a^+$ (myeloid)	$CD1a^-$ (myeloid)
DC localization		Mucosal DC
Cytokine status	High IL-12 Low IL-10	Low IL-12 High IL-10 High IL-6

induce stable IL-12 production by DCs, for example, high doses of antigen, IFN-γ, or IL-4. Interestingly, monocyte-derived DCs prime strong T_{H1} responses early after onset of maturation, whereas at later time points, the same cells prime T_{H2} or T_{H0} responses. Likewise, when DCs stimulate naive T cells at low stimulator/responder ratios, T_{H2} polarization is favored despite the presence of IL-12. Recently, it was proposed that different developmental lineages of DCs could induce either T_{H1} or T_{H2} responses, hence the terminology DC1 or DC2 (Fig. 10) was introduced. Monocyte-derived or myeloid DCs were thought to prime T cells towards the T_{H1} phenotype, whereas plasmacytoid DCs were believed to exclusively prime towards the T_{H2} phenotype. However, this is not the case, as evidenced by at least two recent observations: CD1a-negative subpopulations of monocyte-derived DCs do not secrete IL-12, even after stimulation with LPS, IFN-γ, or CD40L. Likewise, plasmacytoid DCs can be very potent in priming naive T cells towards T_{H1} differentiation, especially after viral infection.

In conclusion, T helper cell priming by DCs is very flexible, allowing the simultaneous generation of T_{H1}, T_{H2}, and T_{H0} responses.

10.6 Immune Evasion and Plasticity of DCs

In general, DCs, after having met viruses or other pathogens, will mature and secrete IL-12, thereby skewing T_{H1} differentiation. However, infection of immature human DCs with herpes simplex virus type 1 (HSV-1) or vaccinia virus has been shown to inhibit DC maturation. Likewise, the bacterial metabolite n-butyrate, which is found in high concentrations in the gastrointestinal tract, can interfere with LPS-induced IL-12 release, but not of IL-10. IL-10 released during infection with *Bordetella pertussis* not only promotes the differentiation of monocytes into macrophages but also the differentiation of T regulatory cells, which suppress protective T_{H1}

responses (Fig. 14). In response to viruses and *Streptococcus pneumoniae*, DCs can activate B cells via secretion of proinflammatory type 1 interferons, thereby promoting immunoglobulin isotype switching. Most recently, it has been observed that there are reciprocal activatory interactions between NK cells and DCs. The cross talk between both cell types appears to be relevant in innate antitumor responses.

10.7 DCs in Immunotherapy

The superior role of DCs in triggering antigen-specific T-cell responses has provided the rationale for developing new vaccination strategies based on the injection of DCs loaded with antigen *in vitro*. In most immunotherapy protocols, autologous $CD34^+$ precursor-derived DCs or monocyte-derived DCs from healthy volunteers or patients are being used.

In vaccination against tumors, the ultimate goal is to prime $CD4^+$ and $CD8^+$ T cells with antitumor reactivity. To achieve this, efficient and stable loading of MHC molecules of DCs with cognate tumor antigens is necessary. Two strategies are employed to provide antigens: an endogenous and an exogenous way. Endogenous antigen expression was obtained by using bulk RNA prepared from tumors or retroviral, adenoviral, or poxviral vectors to transduce DCs with genes coding for the respective tumor antigens. Another

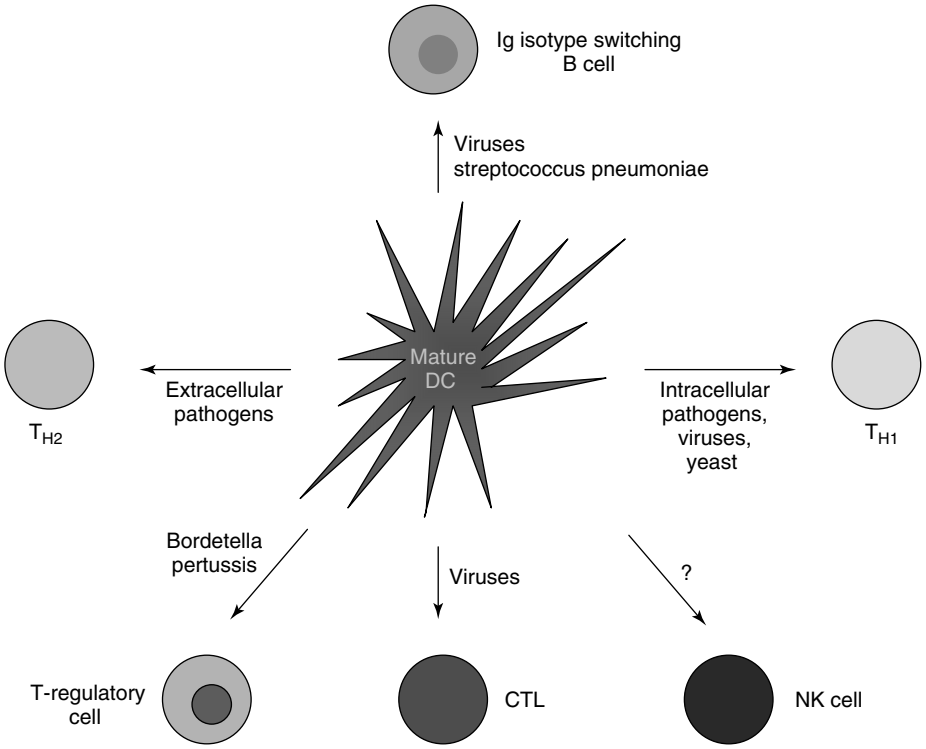

Fig. 14 The plasticity of DCs. Mature DCs in the draining lymph node are capable of delivering different signals according to the microbes they encounter in the periphery.

approach to obtain endogenous antigen synthesis in DCs has been to fuse DCs to tumor cells. The immunogenicity of such vaccines was confirmed in several experimental systems, although the mechanisms leading to the clinical success of allogeneic approaches remained open.

The alternative strategy foresees to provide tumor antigens exogenously. To this end, tumor cell lysates and defined tumor antigens, applied as a protein or a peptide, were coincubated with autologous DCs so that MHC class II–restricted peptide antigens become cross-presented. An alternative to this latter strategy is to prepare exosomes from the respective tumor cells. Exosomes are the internal vesicles of multivesicular endosomes. They were shown to contain tumor rejection antigens and to be able to transfer them to DCs, so that tumor-specific CTL responses are generated in mice. Although several clinical trials – where DC-based vaccination was employed in the context of malignant melanoma, lymphoma, myeloma, prostate, and renal cancer – were successful to a certain extent, there are still several potential caveats that have to be taken into account. Some tumor antigens are not tumor-specific but tissue-specific and hence widely expressed in normal tissues. In case of vaccination with melanocyte/melanoma antigens, this leads to vitiligo due to autoimmunity at the vaccination site. Conversely, the immunoproteasome of DCs may process tumor antigens in a way that is different from processing by the normal proteasome being active in tumor cells. Moreover, feeding DCs with whole tumor cell lysates is risky since T cells that are not directed against tumor antigens may be primed as well. Therefore, precise knowledge of MHC class I–and MHC class II–associated tumor-specific peptide antigens is necessary. Unfortunately, only a few class II–restricted helper epitopes are known so far. Therefore, further effort is needed to obtain a more comprehensive set of tumor-specific peptide epitopes in order to optimize DC-based vaccination against major malignancies.

Keywords

Anneal (hybridize)
To form doubled-stranded oligo/polynucleotides (duplex) from two complementary single-stranded polynucleotides by heating and cooling.

Antisense
A strand of DNA that has the same sequence as mRNA (coding strand).

Ribozyme
Nucleic acid polymer (RNA) that catalyzes a chemical reaction, mostly transesterification.

RNase H
A ribonuclease that recognizes and cleaves internally the RNA strand of a DNA–RNA hybrid.

RNAi
RNA interference, a natural process whereby small double-stranded (21-mers) RNAs induce gene silencing.

Phosphorothioate
Oligonucleotides in which one of the nonbinding oxygens on phosphorus is replaced by sulfur.

Backbone
Refers to the sugar–phosphate linkage in DNA or RNA that can be replaced by isosteric linkages.

Antisense technology is a novel method for drug discovery and drug development. Antisense oligodeoxynucleotides (ODN) work at the genetic level by inhibiting the translation of disease-causing proteins.

Proteins are the key players in the etiology of diseases. Especially for cancer and viral infections, the antisense technology shows promise. The underlying mechanism of this approach is to sequence-specifically interfere in the genetic flow at the mRNA level. This molecular recognition is believed to rely on Watson–Crick base pairing

between the mRNA and the antisense oligonucleotide. Different modes of action are to be considered. The ODNs can either simply function as a steric block to interfere with the ribosomal translation or induce the action of particular RNases to destroy the mRNA in the hybrid formed with the ODN. In addition to this pharmacodynamic consideration, pharmacokinetic processes are important for optimal drug activity. Key points are the mode of delivery of the ODNs to the patient, to assure that the target is reached in the cells or organs of concern. The synthesis of the oligonucleotides has to be straightforward, economic, and reliable. The ODNs should be fairly metabolically stable, possess high affinity to the target, be nontoxic, and preferentially orally available. The first generation of ODNs are the phosphorothioate analogues that have been extensively tested. However, further developments of analogues for improvement are actively pursued.

This article will feature the design of oligos, their synthesis, modifications, and a discussion of the mechanisms of action. The ODN application will be illustrated with some selected examples, with the emphasis on those that are in clinical trials.

1 Introduction

The classical treatment of a disease is the inhibition of function of the protein that is presumed to be the causative agent of the disease, mostly with a small molecular weight drug. Even though this concept is very successful, problems arise when the drug is not very specific for the protein in question, for example, when the wild type and the mutated protein are not sufficiently different in their affinity for the drug. Thus, the idea to interfere earlier in the process of disease development by preventing the synthesis of the unwanted protein at the first place is attractive. It is based on the idea that the wild type and the mutated protein are sufficiently different in their nucleotide sequence that it should be possible to sequence-specifically inhibit either transcription or translation for the latter but not the former. The antisense methodology follows the route of translation interference. This approach has been applied beyond gene functional analysis to application in the clinic where a considerable number of trials are underway.

In the original concept, the antisense method for the sequence-specific inhibition of gene expression was quite simply steric blockage of translation by binding of the oligonucleotide (ODN) to the mRNA target. However, it is now generally accepted that the mode of action is more complicated. Even though some of the chemically modified antisense oligonucleotides (AS-ODN) seem to act by this mechanism, the most commonly used AS-ODN act by degradation of the RNA target by RNase H in the hybrid formed upon annealing of the AS-ODN. As it was recognized early that the unmodified ODNs are unsuitable for most *in vitro* and certainly for *in vivo* applications, chemical modification has played a major part in developing this methodology. The phosphorothioate analogues have played a crucial role in this development.

More recently, RNA interference has been described for the inhibition of gene

expression, which will be discussed later in a separate section.

The antisense oligodeoxynucleotide approach has been reviewed recently. A very thoughtful review of the different types of inhibition of gene expression with oligonucleotides has also appeared recently.

2 Chemical Modification of Oligonucleotides

2.1 Unmodified Oligonucleotides

Natural oligodeoxynucleotides are widely used as tools in molecular biology; however, they have serious limitations in their application as therapeutics for the sequence-specific inhibition of gene expression. Such oligonucleotides with a natural phosphodiester internucleoside linkage are degraded in serum within minutes to a few hours, mainly by the action of fast-cleaving 3′-exonucleases that are accompanied by slower-cleaving endonucleases. In certain tissues, a significant 5′-exonuclease activity has also been observed. However, oligonucleotides can be protected against nucleolytic cleavage by packaging into liposomes or nanoparticles that, at the same time, serve as carriers for *in vivo* application of these compounds as discussed below.

2.2 Phosphorothioates

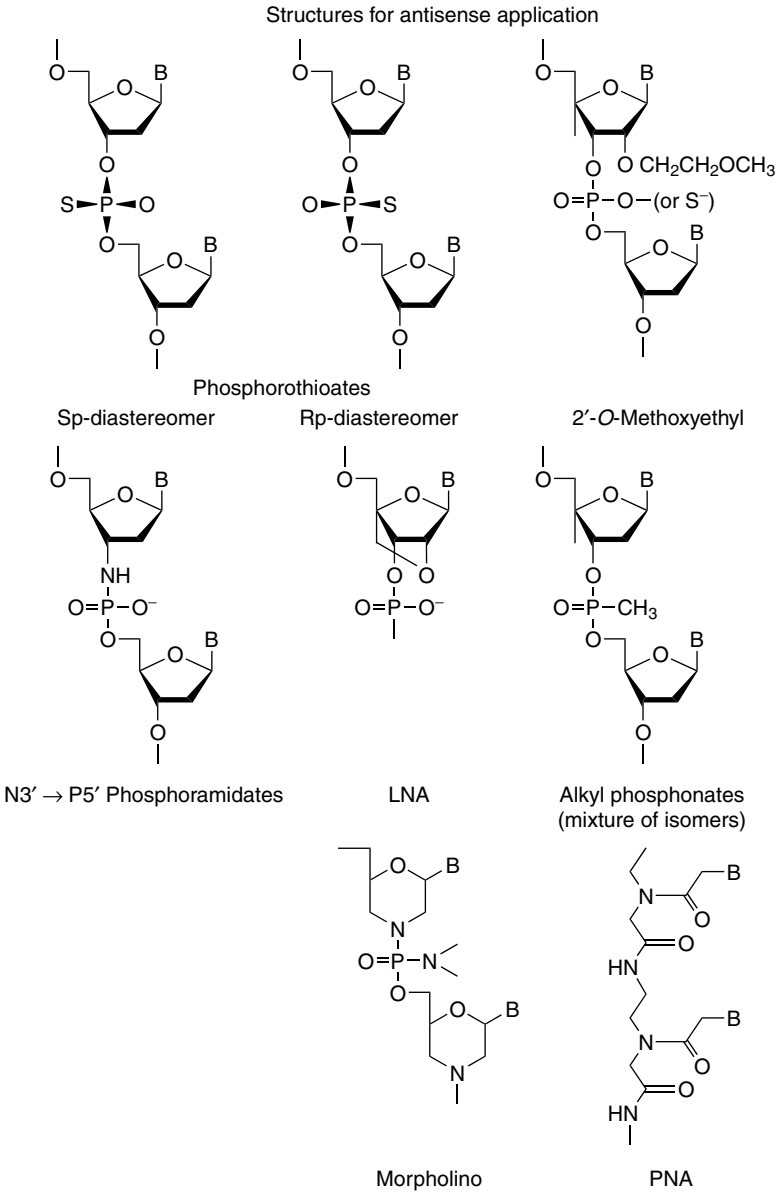
Because of the nuclease sensitivity of ODNs, the major aim from the beginning was to strengthen the stability against such degradation by chemical modification. The first such modification was the introduction of phosphorothioate groups as internucleotidic linkages, which has been quite successful so that most antisense oligonucleotides (AS-ODNs) in use are the phosphorothioate analogues. This modification indeed enhances the stability of the ODNs against enzymatic degradation and at the same time is compatible with activation of RNase H. Thus, these analogues look ideal but unfortunately they have some drawbacks. Thus, the thermal stability of the complex formed with the target RNA is not as stable as that formed with an unmodified oligonucleotide. Moreover, for reasons that are not well understood, the phosphorothioate ODNs can have a much higher affinity to certain proteins such as those responsible for polyanion binding. This can result in undesired side effects often associated with cytotoxicity. Thus, reducing the number of phosphorothioates in an AS-ODN is advisable and will be discussed below.

As replacement of one of the nonbridging oxygens of the internucleotidic phosphate results in a chiral phosphorus, the chemical synthesis of the ODN results in a mixture of diastereomers unless efforts are undertaken to render the synthesis stereospecific, which is possible but not routinely done. There does not seem any particular advantage for either isomer in terms of the combination of thermal stability and RNase H activation over the mixture.

In summary, the advantages of the phosphorothioate modification outweighs the disadvantages at least up to now, making them a first generation of AS-ODNs.

2.3 Alkylphosphonates

Rather early, it was assumed that the negative charge of the phosphate backbone of the ODNs might interfere with



cellular uptake, and thus constructing ODNs with a neutral backbone was attempted. Representatives for such analogues are the methylphosphonates in which the negatively charged phosphate oxygen is replaced by a neutral methyl group. These analogues have been used very early for antisense inhibition of gene expression. They are available through automated oligonucleotide synthesis using methylphosphonamidites as synthons. The methylphosphonate linkage is highly

stable to degradation by nucleases. As in the phosphorothioates, the methylphosphonates exist as two diastereomers of the Rp or the Sp configuration. Uniformly methylphosphonate-modified oligonucleotides do not form duplexes with RNA to induce RNase H cleavage. However, chimeric oligonucleotides containing both methylphosphonate and a window of at least five to seven phosphodiester linkages retain RNase H activity. This class of ODNs has not been very useful for the inhibition of gene expression. Besides the lack of RNase H activity, it also turned out that, contrary to expectation, cellular uptake is more sluggish than that of ODNs with a negative charge.

2.4
2′-*O*-Modification

In order to limit the number of phosphorothioates in an AS-ODN, alternative modifications were sought to enhance enzymatic stability without the inherent side effects of the phosphorothioates. It was recognized early that alkylation of the 2′ position of the ribose indeed increases stability. Thus, 2′-*O*-methyl modification was used, followed by the 2′-*O*-methoxyethyl derivatives. These analogues adopt an RNA-like (A-form) conformation, assuring high binding affinities for the RNA target and thus being superior in this respect to the phosphorothioates. As such, 2′ modification does not support RNase H activity (see below). The general policy is to locate them at the flanks of an AS-ODN, leaving a gap of approximately six to eight phosphorothioate nucleotides in the center to take advantage of RNase H activity. Thus, the second-generation oligos of the ISIS company have 2′-methoxy-ethoxy moiety termed *MOE-Oligos*. Often, particularly for animal model application, even the flanks contain the phosphorothioates to further improve stability. Apparently, in conjunction with a 2′alkyl modification, the cytotoxic side effects of phosphorothioates are not severe.

2.5
Sterically Locked Nucleic Acids

Nucleic acid analogues with conformationally restricted sugar–phosphate backbones have been attractive as it was envisaged that they might form more-stable duplexes for entropy reasons. Thus, the DNA analogue bicyclo-[3.2.1]-DNA has a rigid phosphodiester backbone, emulating a B-DNA-type conformation, to which the nucleobases are attached via a flexible open-chain linker. Although bicyclo-[3.2.1]-DNA forms less-stable duplexes with complementary DNA than natural DNA, base-mismatch discrimination is slightly enhanced compared to pure DNA duplexes. Importantly, bicyclo-[3.2.1]-DNA oligomers are resistant to 3′-exonuclease degradation. None of these analogues has been tested for inhibition of gene expression yet.

A further development along these lines are the locked nucleic acids (LNA), which represent a totally new and very promising class of compounds. In these analogues, the 2′ oxygen is linked by a methylene bridge to the 4′ carbon, forming a methylene-linked bicyclic ribofuranosyl nucleoside. These analogues, like the 2′-*O*-alkylated oligoribonucleotides, adopt an RNA-like (A-form) conformation and thus bind very well to target RNA. Probably not surprisingly, they are not substrates for nucleases. Oligonucleotides consisting purely of LNA units do not activate RNase H, but LNA/DNA chimeras do. Thus, these analogues combine many favorable

features for application. Although some cell culture data have been published, further studies should demonstrate the advantages of this class of compounds in a wider setting, in particular, in animal model studies.

2.6
N3′-P5′-Phosphoramidates

Oligonucleotides based on this structural element also show remarkable resistance to nucleases but do not activate RNase H. Extensive studies for the inhibition of gene expression are still awaited.

2.7
Morpholino Oligonucleotides

This class of compounds again is RNase H–irresponsive but, of course, is very stable to nucleases. It has found acceptance mainly in developmental studies in the zebra fish and Xenopus, both systems in which the compounds can be administered (injected) to the embryo. For other *in vivo* studies, uptake of the compound seems to be limited, as discussed below.

2.8
Peptide Nucleic Acids (PNA)

Peptide nucleic acids (PNA) deviate from all other analogues in that the linkage between the monomeric units is a peptide bond and not a phosphodiester bond. They show excellent affinity to RNA targets and thus should be ideally suited for interference with gene expression, even though they cannot rely on RNase H activity to destruct the target. Some cell culture data have been published, but further studies are desired to fully appreciate the potential of this class of compounds.

2.9
Oligonucleotide Conjugates

Certain properties of ODNs can be influenced by the covalent attachment of nonnucleosidic moieties to either the 3′ or 5′ ends. This type of derivatization allows modulation of nuclease stability, cellular uptake, and organ distribution of ODNs. In addition, the internucleoside linkages, the C5 position of pyrimidine bases, and the 2′ position of ribose are also positions for derivatisation, but these will not be considered here.

2.10
5′-end Conjugates

Conjugation of molecules to the 5′ end of ODNs is straightforward by coupling a phosphoramidite or H-phosphonate derivative of the desired molecule to the 5′-hydroxy group of the oligomer, following chain elongation by solid-phase synthesis. A broad range of phosphoramidite derivatives of ligands, such as fluorescein, biotin, cholesterol, cholic acids, dinitrophenyl, acridine, and psoralen derivatives, are commercially available. Alternatively, the 5′-terminal hydroxy group of the oligonucleotide is reacted with an aminoalkyl linker phosphoramidite, which, after deprotection, results in a free aminoalkyl function. This amino function can then be reacted in solution with suitably activated conjugate molecule derivatives, such as active esters, isothiocyanates, or iodoacetamides.

2.11
3′-end Conjugates

The conjugation of molecules to the 3′ end of oligonucleotides is achieved by using appropriately functionalized solid supports

that, in addition, harbor a hydroxyl function from which the oligonucleotide chain is extended during solid-phase synthesis. After oligonucleotide synthesis is complete, the oligonucleotide conjugate is cleaved from the solid support and deprotected by ammonia treatment. Similarly to the 5′-conjugation, appropriate 3′-amino-modifier solid supports are commercially available, which allow coupling of suitably activated derivatives of the molecule to be conjugated with the 3′-amino alkyl group in a postsynthetic solution-phase step.

3 Mechanism of Action

For most of the AS-ODNs, activation of RNase H is the mechanism of action to interfere with translation. This enzyme recognizes a duplex between DNA and RNA, resulting in the cleavage of the RNA strand of this duplex. The essential role of this enzyme in inhibiting gene expression is based on the observation that the target RNA is degraded, which would not be expected if a simple blockage of translation, as originally conceived, was the mechanism of inhibition of translation. The most convincing evidence that the enzyme RNase H is responsible for this degradation relies on the fact that AS-ODNs that are incompatible with the action of this enzyme do not result in degradation of the mRNA. This enzymatic step, of course, makes AS-ODN turnover a key step in the process requiring, in principle, substoichiometric amounts of the oligonucleotide for complete destruction of the RNA.

Activation of RNase H demands a DNA-like or B-conformation of the ODN. This requirement is obviously best met by oligodeoxynucleotides as they exist in this conformation. However, DNA–RNA complexes are not as stable as RNA–RNA complexes, which makes ODN with an RNA-like or A-conformation more desirable for hybridization with RNA. This criterion is met by the 2′-alkylated ODNs and the LNAs, which indeed show high thermal stability. Thus, there is a dilemma in that one conformation is most suitable for one of the desired properties that is, unfortunately, not optimal for the other. The phosphorothioates apparently represent a good compromise for these two qualities. As mentioned above, the alkylated analogues do not activate RNase as the 2′ group interferes with recognition by this enzyme or prevents substrate cleavage.

Neither the 2′ alkylated analogues, the alkylphosphonates, the morpholino, the N3′-P5′-phosphoramidates, nor the PNAs activate RNase H, but they do show inhibition of gene expression. The simplest explanation is that they follow the original concept in physically blocking translation by preventing the ribosome either to bind at the entry site or to move along the mRNA. Alternatively, the oligo may replace one strand in a duplex. Whether this is a sufficient explanation or whether other factors are involved remains to be seen.

4 Positioning

An important factor in obtaining efficient inhibition of gene expression is the positioning of the AS-ODN on the mRNA. The secondary structure of the latter will have regions that are more suitable than others for the annealing process. Although a number of computational methods exist to predict such regions, many researchers prefer experimental approaches to identify such positions. The method based on the

annealing of a randomized oligodeoxynucleotide preferably to the native RNA and subsequent cleavage by endogenous RNase H is the nearest to the intracellular situation and yet is relatively simple to perform. In any event, in most cases a number of AS-ODNs will be synthesized to select the most active. Depending on the laboratory, this number can be up to twenty.

5 Delivery

One of the problems for the antisense strategy is the intracellular availability of the negatively charged oligonucleotides with a molecular weight of several thousand daltons. ODNs are usually not taken up efficiently in cell culture. Electroporation is one way of delivering the ODNs to the cell, but this method is not of general applicability. The most commonly used strategy for cell culture experiments is the complexation of the oligonucleotides with synthetic lipsosomes with a positive charge on the surface. A large variety of these compounds are commercially available. These carriers by themselves are usually toxic to the cell because of the positive charges, but once covered by the ODN this cytotoxicity is in most cases abolished. Transfection efficiencies can widely differ, but this can be monitored by cotransfection with a fluorescent ODN. In most cases, the ODNs are trapped to a considerable degree in the endosome so that only a fraction is located in the cytoplasm or in the nucleus, places where they should be operative. Most interesting is the observation that uptake of ODNs *in vivo*, that is, in animal models or even man, does not require such carriers. The delivery there is simply achieved, for example, by subcutaneous or intravenous infusion. This difference for *in vitro* and *in vivo* cellular uptake signifies a considerable difference between the two systems, which is not understood at present. Whatever the cause of it, it should caution for extrapolating from the *in vitro* results to *in vivo* relevance. Independent of the method of delivery, considerable efforts are spent on directing the ODNs specifically to the desired cell or organ type.

Uptake of the ODNs with a neutral backbone such as the morpholinos or the PNAs cannot rely on cationic carriers because of lack of binding. They require cell scraping, injection, or, as shown for PNA, conjugation with cationic peptides to facilitate cellular uptake. At present, this presents a certain barrier for wide application, in particular, for medical purposes.

6 Application

The literature on the application of ODNs for the inhibition of gene expression is vast.

We have summarized in Table 1 those examples in which the technique has advanced to clinical-phase trials, although this collection is probably not complete. Not surprisingly, considering the enormous expense involved, these investigations are almost exclusively conducted by companies. The only notable exception is the study by the laboratory of A. Gewirtz on CML for *ex vivo* treatment.

Not all the examples listed can be discussed here, so some comments must suffice. Common to all ODNs used in the clinical trials is one aspect of their chemical nature in that they all are phosphorothioate-containing ODNs. The first approved antisense drug was developed by ISIS, Fomivirsen or Vitravene, a trade

Tab. 1 Antisense drug pipeline.

Target	*Lead indication*	*Company*	*Product*	*Phase*
CMV	CMV-retinitis	ISIS	Vitravene	Drug
PKC-α	Cancer-NSCLC	ISIS/Lilly	Affinitac	III
C-RAF	Cancer-ovarian	ISIS	ISIS 5132	II
H-ras	Cancer-pancreatic	ISIS	ISIS 2503	II
ICAM-1	Crohn's disease	ISIS	ISIS 2302/Alicaforsen	III

HCV	Hepatitis C	Ribozyme Pharmaceuticals	Heptazyme	I
HER2	Cancer	Ribozyme Pharmaceuticals	Herzyme	I

name of Novartis, certainly a fantastic achievement. However, the number of patients with CMV-retinitis has grown lesser and lesser because of the successful treatment of AIDS at least in the Western hemisphere. ICAM-1 from the same company, as a medication for Crohn's disease, has not been approved yet but is pursued further under the trade name Alicaforsen. Very far advanced is the Genta anti-*BCL2* oligonucleotide Genasense for the treatment of malignant melanoma in conjunction with chemotherapy. Genasense is in phase III clinical trial, developed together with Aventis.

Affinitac is a potent inhibitor of PKCα in non–small cell lung cancer, which shows almost double survival times (16 instead of 8 months) in combination with carboplatin/taxol. The main objective is to obtain a good synergistic profile by the combination with chemotherapeutic agents, as is the goal with Genasense, with taxol in this case. Affinitac is also tested in a single-agent (phase II) trial against non-Hodgkin's lymphoma. Here, a codevelopment together with Eli Lilly is under way.

7 RNA Interference

Inhibition of gene expression by RNA interference is a rapidly growing area of research and has already found considerable application for gene functional analysis. It differs from the antisense method fundamentally. It is a natural process in plants undergoing transgene- or virus-induced posttranscriptional gene silencing (PTGS). Here, short double-stranded oligoribonucleotides are processed from long dsRNA for the inhibition of expression of the foreign gene.

This process has now been extended to many organisms, mainly in cell culture but also in a few animal model studies for gene function analysis. It requires double-stranded oligoribonucleotides 21 nucleotides in length (called *siRNAs*) of which one strand is completely complementary to the mRNA target. Upon binding of this strand to the mRNA in a RNA induced silencing complex (RISC) complex, the target is cleaved opposite the oligoribonucleotide. The breakthrough in the field came by the observation that the oligonucleotides can be added exogenously, thus facilitating wide application. They can be chemically synthesized or obtained by *in vitro* transcription to be transfected with the aid of a carrier as detailed earlier. Alternatively, vectors can be constructed for stable transfection where the sequence of the oligonucleotides is positioned, most often behind the U6 promoter, for intracellular transcription. The inhibition by the siRNAs is not very dependent on the secondary structure of the mRNA. Usually three constructs are sufficient to identify the most active oligonucleotide pair, thus much fewer than that required for the AS-ODNs as described earlier. Also, in general, the inhibition achieved is very satisfactory.

8 Ribozymes

Although not normally considered in the context of the antisense methodology, ribozymes fall into this category as the basis for their interaction with RNA is based on the sense–antisense principle. The fundamental difference between the classical antisense method and that of RNA interference is that ribozymes have the inherent catalytic power to cleave the target RNA rather than to have to rely on cellular proteins for this step. Ribozymes will not be discussed here in depth, but two recent reviews give an excellent account of the present understanding of the various types of ribozymes. Some clinical trials are ongoing that are predominantly directed against Hepatitis C (Heptazyme), the VEGF receptor (Angiozyme), and the human epidermal growth factor HER2 (Herzyme).

9 Conclusion

This review demonstrates that the antisense methodology is not as simple as originally anticipated. As research progresses, more and more insight is gained into the complexity of responses induced by the insertion of an oligonucleotide in a cell. Given these problems, it is a great achievement that quite a few ODNs are now in clinical trials. It provides encouragement to pursue this line of development further. With the knowledge available from past experience, it is expected that the pace of the development of oligonucleotide-based drugs will accelerate.

Keywords

Callus
A mass of disorganized plant tissue, generally with low degree of cell differentiation, usually cultured on solid media.

Cell Suspension
Cells derived from callus or explant tissue and cultivated in liquid media, usually proliferating cell aggregates or single cells.

Explant
The portion of the intact plant used to initiate callus cultures.

Taxane
A compound related to taxol that can be described as a diterpene composed of three pentadecene rings.

Taxol™ (general name Paclitaxel)
A diterpene amide with antineoplastic properties.

Taxus
A genus of gymnosperm trees belonging to the family Taxaceae and commonly known as yew.

Taxol™ is an anticancer drug increasingly used for the approved treatment of various cancer types, including ovarian, breast, lung, head and neck, bladder and cervix, melanomas, and AIDS-related Karposi's sarcoma. The supply of this compound is limited because of expanding demand and the fact that the only commercial source is the biomass of *Taxus* species. Yew trees grow relatively slowly, contain low and variable amounts of Taxol™, and in many cases are located in protected, environmentally sensitive areas. The bulk of current Taxol™ production derives from semisynthesis starting from 10-deacetyl baccatin III, a precursor obtained from yew needles. Cell culture of yew species is a viable alternate source of Taxol™ and related taxanes, which can be used for production and/or semisynthesis of the drug. Cell cultures are readily renewable and yield relatively homogeneous, easily manipulated systems for biosynthetic studies on Taxol™, amenable to large-scale commercial production.

1
Plant Material Selection and Preparation

1.1
Type and Source of Explant

The procedures described here were established primarily from results obtained with *Taxus cuspidata* (Japanese yew), although some studies were performed using *Taxus canadensis* and *Taxus brevifolia*. In general lines, variations of these procedures have been successfully applied to a number of other *Taxus* species. In the recent literature of taxane production by yew cell culture, preference has been given to *T. chinensis*, *T. media*, *T. cuspidata*, and *T. canadensis*.

The response of yew tissue to *in vitro* culture is dependent on the type of explant used to initiate the culture, on the physiological status of the donor plant, and on its genetic makeup. Explants that contain meristematic or parenchymal tissue are preferable. These are the types of tissue most likely to display cell proliferation in response to the growth regulators in the culture medium, and this tendency is attributed to these tissues' low degree of differentiation, which seems to be associated with a certain developmental flexibility in the presence of the appropriate stimuli. Relatively more differentiated tissues, such as sclerenchyma or xylem, are less responsive to exogenous plant growth regulators, possibly because of the genetic commitment to a specialized developmental pathway.

Young stem segments (flexible, but bearing dark green needles) are ideal for rapid initiation of callus to be used in developing cell cultures. Seed contents (megagametophyte and embryo) are better suited for establishing long-term maintenance of callus cultures of *Taxus brevifolia*. Needles are also a suitable explant type for callus initiation, although initial growth rates tend to decrease more rapidly than those of young stem segments. Arils (fleshy basal covering of the seed) display different responses to *in vitro* culture depending on their stage of development. Green arils grow relatively fast for the first two weeks, but from then on, the growth seems to stop. Calli derived from green arils are relatively hard and not friable. Mature red arils, not surprisingly, fail to grow in culture, possibly as a result of the advanced degree of cell lysis at this later stage of their development (Table 1).

The physiological condition of the donor plant must be stable and favorable to growth. Outdoor-grown plants display higher contamination rates and tissue pigmentation when cultures are started in the winter months in Canada (November to March) relative to those started in other seasons. Genetic differences between plants of the same species are also factors to be considered; it may be necessary to test different donor plants to develop *in vitro* cultures. Donor plants of the same species, although grown under similar environmental conditions, may display significant differences in the

Tab. 1 Effect of different explant sources of *T. cuspidata* cultivated in B5 medium (containing 1 mg L^{-1} 2,4-D) on callus formation and growth.

Explant	*Growth*[a]	*Friability*
Green aril	+	No
Red aril	−	−
Seed content	++	Yes
Young stem[b]	+++	Yes
Needle[b]	++	Yes

[a] +, directly proportional to growth; −, poor growth.
[b] Also tested with *T. Canadensis*.

amount of growth *in vitro* as a result of genetic variability. It may also be beneficial to begin *in vitro* culture using plants shown to produce high yields of Taxol™. High taxane yields *in vitro*, however, are not always warranted by this phenotype in explant donor plants.

1.2 Sterilization Procedure

Sterilization is accomplished using standard plant tissue culture techniques. The tissue is washed with distilled water to remove dust and solid particles, immersed in 70% ethanol for one minute, immersed with a few drops of Tween 20 (surfactant agent) in NaClO (1.5% v/v) for 30 minutes, and rinsed three times with sterile distilled and deionized water. During the sterilization period, the tissue must be kept fully immersed and under agitation. Sterilization times may have to be reduced for more sensitive and tender tissues. Our experience has yielded typical contamination rates using outdoor-grown donor plants that are less than 3% of the total number of explants used. In winter, however, the incidence of contamination can be 10 times the regular rate. In certain cases, a particular plant may be extensively infested with endophytes that are not destroyed by surface-sterilization procedures; in this situation, contamination can be very high and a change of donor plant is advisable.

1.3 Explant Size and Final Preparation

Following sterilization, the exposed cut portions of the tissue that were damaged by the ethanol and NaClO solutions are excised, and the healthy tissue is appropriately trimmed and placed in the growth medium. Excision of explants should be made smoothly, with a relatively new blade, to minimize the production of phenolics in the cut areas. In the case of stem segments, approximately 1-cm long segments give good results. Stem segments can be cultured at an approximate angle of 45° to the agar surface, with one of the transversely sectioned ends immersed in the medium and the other partly exposed to the air of the culture vessel. Alternatively, longitudinally cut stem segments can be cultured with their cut portions facing the surface of the medium. The contents of longitudinally halved seeds can be placed on the medium after separation from the seed coat with a spatula. Isolated embryos can be used instead, in order to avoid calli derived from the haploid megagametophyte tissue; haploid tissues, on the other hand, may be useful for mutant generation and screening. Hypocotyl segments or other portions of aseptically germinated seedlings are also good sources of explants. Yew tissues seem to be very sensitive to heat, relative to tissues of other woody plants. All tools used in explant preparation and cell transfer should be sterilized in ethanol, flamed briefly to remove ethanol residue, and cooled to room temperature before touching the plant material.

2 Establishment of Callus and Cell Cultures

2.1 General Procedure

Cultures of yew are relatively difficult to establish because growth rates are slow and the explants produce and release phenolics; in turn, the oxidation of the phenolics leads to darkening, growth

inhibition, and eventual loss of viability of the tissue. The inclusion in the medium of phenolic-binding compounds, such as polyvinylpolypyrrolidone (PVP), improves the growth of the explants. The inclusion of activated charcoal in the media can also reduce darkening, although it may also diminish explant growth as a result of binding of medium components. In addition, transfers to fresh medium (or rotation of the explants to new positions in the culture vessel containing portions of unused medium) at approximately 15-day intervals help prevent growth inhibition due to phenolic oxidation.

More frequent transfers may be required in the early period of cultivation or when the donor plant is more prone to darkening upon *in vitro* culture. After several subcultures and growth stabilization of the cultures, the need for phenolic-binding adjuvants may decrease or even disappear.

Following an initial screening and evaluation of some standard medium formulations, the basic medium B5bPVP was established for callus initiation in yew; it consists of B5 medium salts and organic supplements, 3.0% (w/v) sucrose, 1.5% (w/v) insoluble PVP, 0.8% (w/v) agar, and 1 mg L^{-1} of 2,4-dichlorophenoxyacetic acid (2,4-D). The media are prepared with distilled and deionized water, plant cell culture or reagent-grade chemicals, adjusted to pH 5.8 with NaOH and HCl (after the addition of PVP and prior to the addition of agar) and autoclaved (1.1 kg cm^{-2} at 121 °C for 20 min).

Preferably, the glassware used for plant cell culture should be washed with neutral detergent, abundantly rinsed with tap water, and then rinsed with distilled water. The cultures can be grown in plastic petri dishes (9 cm in diameter) containing 30 mL of medium (3–4 explants per plate) and sealed with parafilm™ or air permeable tape, or in 30 mL glass vials with polypropylene or aluminum foil lids containing 10 mL of medium each (1 explant per vial). The cultures are incubated at 25 °C in dark. Various other media formulations based on MS, WPM, SH and B5 salts and organics supplemented with auxins and cytokinins have been effectively used for several *Taxus* species.

2.2 Medium Optimization

Additional improvements on the basic medium formulation for yew tissue culture can be accomplished by investigating several medium components (e.g. plant growth regulator balance, salt and organic supplement composition) that promote the growth of related species, or seem likely to have a stimulatory effect on the putative biosynthetic pathway to Taxol™. The effect of the medium components when included in various amounts in the basic formulation, or when replacing some of its original constituents, can be analyzed relative to growth and Taxol™ yield in developing yew calli. Medium factors with a positive effect on growth and Taxol™ yield are combined in new formulations to investigate the possibility of synergistic or antagonistic interactions.

A great deal of work is entailed in the high number of treatments and respective replicates needed for accurate statistical analysis, but these comprehensive experiments allow the identification of limiting factors for growth and Taxol™ production. The overall analysis of the results also shows the relationship between growth and Taxol™ production. From such a series of experiments, two improved media formulations were devised: B5bPhe (B5bPVP with 0.1 mM of phenylalanine)

and B5Phe8/0GA (B5bPhe salts and organic supplements with 8.0 mg L^{-1} of 2,4-D and 0.5 mg L^{-1} of gibberellic acid). After autoclaving, gibberellic acid (GA3) is added to the culture medium by filtration through 0.22-µm sterile filters. All other medium components are added prior to autoclaving. The overall analysis of the results showed a trend toward an inverse relationship between Taxol™ production and growth in the developing callus cultures.

Cell suspension cultures can be initiated from approximately two-month-old callus cultures developed from stem segments. Depending on the availability of callus biomass for inoculum and on incubator space, cell cultures can be grown in 125-, 250-, 500-, and 1000-mL Erlenmeyer flasks containing one-fifth of their total volume of liquid medium. Basic incubation conditions are 22–25 °C in dark on gyratory shakers at 110 rpm. Experiments done in callus and some additional optimization for cell suspension culture medium yielded the following basic formulations: B5 medium salts, threefold the regular amount of B5 organic supplements, 3.0% sucrose (w/v), 1.5% soluble PVP (MW $\leq 40 \times 10^3$), and 1 mg L^{-1} of 2,4-D (B5C1) or the same composition of B5C1, but with a modified balance of plant growth regulators (i.e. 4 mg L^{-1} of 2,4-D and 1 mg L^{-1} of kinetin (B5C2)).

Medium preparation, pH adjustment, and sterilization procedure are the same as in callus culture medium. Insoluble PVP is replaced with soluble PVP in liquid cell cultures to facilitate visual and microscopic observation of the cells and cell harvesting. Inoculum weights are preferably high (e.g. one-third of the volume of the liquid medium) to initially establish cell suspension cultures. After 1 to 2 weeks in culture on a gyratory shaker at 110 rpm, the cells released from the calli are collected and transferred into fresh liquid medium (1 : 1 or 2 : 1 proportion of old to fresh medium). The calli with attendant stem debris can be discarded or replated in solid medium to regenerate more callus tissue. During the first months of culture, the media can be replaced at 2-week intervals following 10 min of centrifugation at 600 × *g* at 20 °C under sterile conditions to pellet the cells; in this way, the maximum amount of cell biomass is saved until the density is great enough to start suspension culture propagation in new flasks. Once suspensions have been stabilized (generally after several cycles of propagation), inoculum amounts can be reduced to one-sixth (w/v) of the liquid medium for propagation of new cell suspension flasks. Transfers to fresh medium in stock cultures can be done every 20 days. Viability checks of newly developing cell lines can be performed via dye exclusion of cells in the presence of Evans Blue (cells staining blue under the microscope are considered not viable) or other cytochemical method, and/or by analyzing the occurrence of growth in microcalli rescued from the liquid culture and plated in solid B5bPVP. Microscopic examination of cell viability and culture sterility should be performed regularly, particularly during the first few months of culture in liquid medium.

Cell cultures can also be immobilized after the first months of culture to facilitate medium replacement and to aid in the establishment of recalcitrant cell lines; this approach has been particularly useful in our efforts to establish *T. cuspidata* cell lines (Fig. 1). Immobilization is performed by spontaneous adhesion to 5 cm × 5 cm, 10- to 15-mm thick glass fiber mats with a uniform diameter of 10 µm and fiber density of approximately 61 mg cm^{-2}.

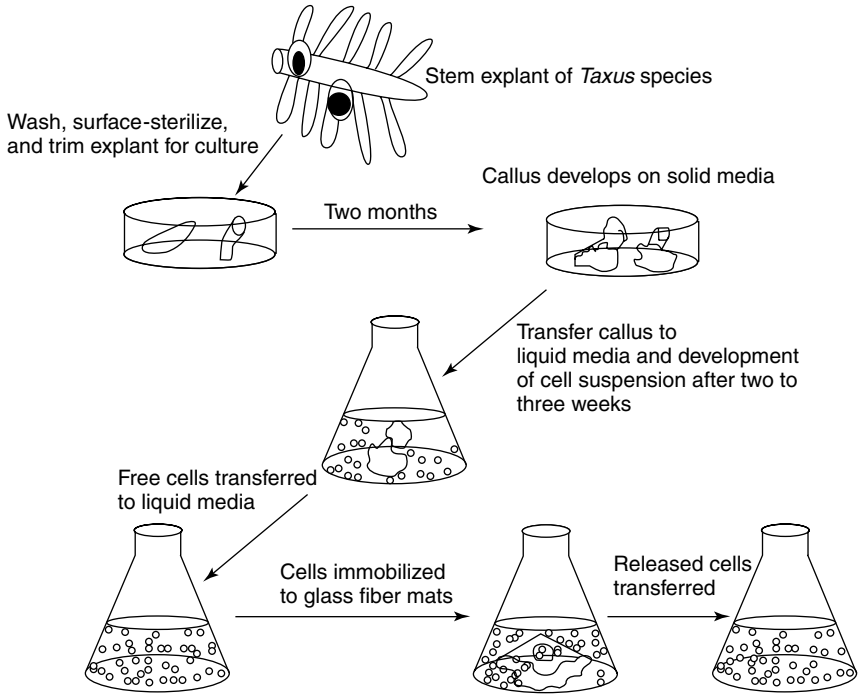

Fig. 1 Establishment of immobilized cell cultures and cell suspension cultures of *T. cuspidata*.

Within the first days of contact with the substrate, the cells are spontaneously immobilized. The cells grow on top of and within the mats, forming several layers of cells; after the cells have saturated the immobilization substrate, they begin to be released into the liquid medium. These cells can be used to establish new suspension cultures or new immobilized cultures. Alternatively, cell cultures can be propagated by carefully removing external cell layers with a sterile spatula, or by cutting the mats in two or four portions and placing these on fresh medium flasks containing a new glass fiber mat (Fig. 1).

Two-year-old cell suspensions of *T. cuspidata* have various degrees of cell aggregation. Moreover, the shape of the cells is variable, from round to considerably long, cylinder-like cells. In general, most cell suspension cultures display a relatively high number of cell aggregates of various sizes, with relatively fewer cells occurring individually. Cell aggregates may constitute a problem in large-scale cell cultures, which can be more susceptible to shear stress and may create difficulties in the mixing of cells, gases, and medium components. It is possible to select for smaller aggregate sizes by allowing larger aggregates to settle for a short period of time and then transferring the smaller aggregates and single cells from the upper portion of the flask into a new culture flask. The selection for the single-cell or small-aggregate type of suspension, however, may have implications for Taxol™ productivity. Aggregated cell suspensions tend to be more productive than suspensions

of the single-cell type, possibly because of their relatively higher degree of differentiation.

In our experience with cell lines of *T. cuspidata*, the stabilization of cell lines is a relatively lengthy process, normally requiring 6 to 12 months for completion. This is not only the case for yew species, but also for many woody species, as a result of their relatively slow growth and often recalcitrant behavior *in vitro*.

3 Analyses of Taxol™ and Taxane Production

3.1 Extraction Procedure

At least 0.5 g of fresh callus tissue or 1 g of fresh cells from suspensions is collected in glass test tubes (previously weighed and identified), frozen (−20 °C), and homogenized with a glass rod in 1 to 2 mL of hexane, followed by 1 h of sonication at room temperature. After 12 h in hexane at 25 °C, the samples are centrifuged at 2500 × *g* for 20 min to pellet the cells, and the supernatants are discarded. The pellets are then extracted in 1 to 2 mL of methanol/dichloromethane (1 : 1) with glass rod rehomogenization, followed by sonication for 2 h at room temperature. After centrifugation at 2500 × *g* for 30 min, the supernatants containing the taxanes are collected; the pellets are used for determining the extracted dry weights at 60 °C until constant weight.

The crude extracts are dried under vacuum or nitrogen at 25 °C, redissolved in 1 mL of dichloromethane, partitioned with 1 mL of water, and centrifuged at 2500 × *g* for 20 min. The dichloromethane fraction is collected, dried under vacuum or nitrogen at 25 °C, redissolved in an exact volume of high performance liquid chromatography (HPLC) grade methanol (100–500 µL), and filtered through 0.45 µm filters for HPLC analysis (Fig. 2).

Alternatively, the tissue can be extracted with 100% methanol. The hexane step can be avoided for cleaner extracts (e.g. cell suspension extracts) or if the column for liquid chromatography to be used in extract analysis is equipped with a precolumn, which prevents irreversible binding of impurities to the column. The Taxol™ extraction step (methanol/dichloromethane, 1 : 1) can be repeated two or three times with the pellet of the first Taxol™ extraction to achieve more complete Taxol™ recoveries. In experiments involving several treatment comparisons and large number of samples with respective replicates, however, a single methanol/dichloromethane extraction step is more practical; this procedure allows for Taxol™ recovery of 80 to 85%. Media from cell cultures can be extracted for Taxol™ with dichloromethane (1 : 1 v/v ratio of medium to solvent). For small volumes, the mixture contained in glass tubes is vigorously agitated on a tube mixer for 2 to 5 min, followed by sonication for an hour at room temperature. The tubes are briefly mixed again and centrifuged for 30 min at 2000 × *g* at 20 °C. For large volumes, the mixture is agitated overnight in flask shakers and partitioned for an hour in separation funnels. The upper aqueous layer is discarded and the organic fraction is dried under vacuum at 25 °C. The preparation for HPLC analysis is similar to the one just described, although the filtering of media extracts tends to be more difficult than in the case of plant material extracts. This difficulty in filtering media extracts prior to HPLC analysis is probably a result of the presence of relatively large amounts of soluble

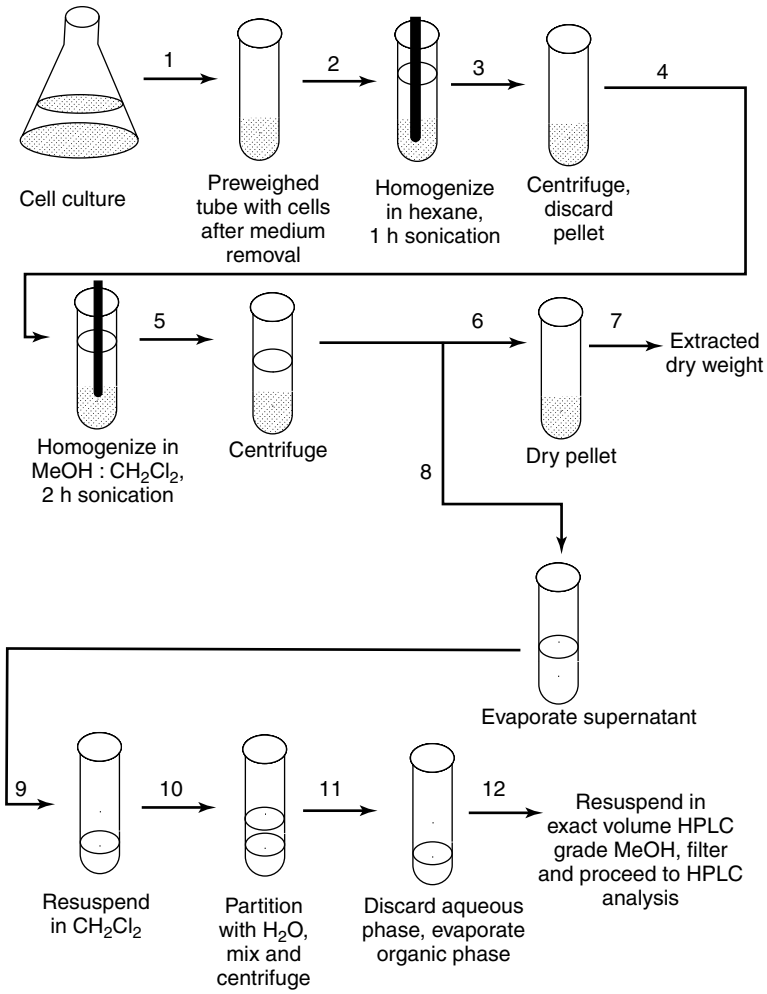

Fig. 2 Extraction of Taxol™ and taxanes from plant material.

PVP in the media. It may be necessary to use larger filters (keeping the pore size at 0.45 μm) and larger volumes of HPLC grade methanol to filter and resuspend extracts of large volumes of medium. Once filtered, these extracts can be further concentrated prior to HPLC analysis. Other alternatives to facilitate medium sample preparation are possible: for example, the removal of PVP by pore size exclusion prior to medium extraction or the substitution of the last filtration step by centrifugation prior to HPLC analysis.

3.2 Separation, Quantification and Identification

The taxane analyses are commonly done by HPLC. There are various chromatographic methods to carry out such analyses. One of these methods is described below.

The samples are passed through a reversed phase microbore column (e.g. Hewlett-Packard ODS Hypersil, 5 µm, 100 mm × 2.1 mm), using a mobile phase containing methanol, water, and acetonitrile; the linear gradient elution profile starts with 20 : 67 : 13 (solvent A), ends with 20 : 27 : 53 (solvent B) within 50 min, and includes a 5-min wash in both solvents to reestablish the initial condition. The flow rate is 0.2 mL min^{-1}, and chromatograms are plotted at 227 nm, using an HPLC system equipped with a photodiode array detector (e.g. Hewlett-Packard 1090A HPLC system). Typical injection volumes are 10 µL, and solvents are all HPLC grade, filtered through 0.45 µm filters prior to use.

Microbore columns have the advantages of high sensitivity, low sample volume, and low solvent consumption. For cell suspension extracts analyzed with the foregoing solvent system, however, a better resolution of early eluting taxanes, such as baccatin III and 10-deacetyl-baccatin III, can be achieved using longer reversed phase analytical columns; in this case, the flow rate is increased to 1 mL min^{-1}, whereas all other chromatographic and detection parameters are not changed.

Quantification is done by the method of external standards, that is, a standard curve is generated with authentic standard (at least five different concentrations covering the concentration range of the extract samples) and run under the same chromatographic conditions as the samples. Taxol™ and taxane identification is done by retention time, UV spectra and, cochromatography with standard. Peak purity checks can be performed as additional evidence for positive identification if the HPLC equipment has a diode array detector.

Further proof of identification can be obtained by collecting the corresponding HPLC peak and performing nuclear magnetic resonance (NMR) analyses. Over a series of injections, a concentrated sample is run through the HPLC system, the corresponding Taxol™ peak in the sample extract is collected and pooled, until approximately 50 µg of Taxol™ has been collected. The collected material is dried under vacuum at 25 °C and resuspended in 150 µL of HPLC grade methanol; then a small portion of it is injected again for purity evaluation and final quantification. If a single peak with the same retention time and UV spectrum as Taxol™ is present in the amount required, the sample is dried under vacuum as before, and freeze-dried for 24 to 48 hours to remove solvent residue. Taxol™ identification, for example, may be obtained by 1H NMR analysis in deuterated chloroform (≈50 µg of HPLC-purified sample Taxol™ in 0.75 mL of deuterated chloroform with 0.05% tetramethylsilane as internal reference) at 500 MHz and 25 °C on a Varian UNITY 500 spectrometer equipped with an inverse detection 5-mm probe. Taxol™ and related taxane standards may be requested for nonhuman research use from the Drug Synthesis and Chemistry Branch, Developmental Therapeutics Program, Division of Cancer Treatment of the National Cancer Institute (U.S.A.). Several taxanes are also available from chemical supply companies.

4 Taxol™ Biosynthesis

Taxol™ is a highly substituted and oxygenated cyclic diterpenoid with a taxane ring system. Its chemical uniqueness among taxanes is due to the presence

of an oxetane ring system, substitution pattern, and the ester side chains. Studies on Taxol™ biosynthesis have been conducted particularly by the groups of R. Croteau and H. Floss in the United States.

Considerable advances have been made both on the biochemical and molecular aspects of taxane biosynthesis. As diterpenes, the taxane skeleton has been shown to be derived from isopentenyl diphosphate (IPP), synthesized via the 1-deoxy-D-xylulose-5-phosphate (DXPS) pathway, on the basis of ^{13}C labeled glucose studies. This plastidic pathway functions in parallel with the classic mevalonate dependent route, which is now believed to be responsible for the assembly of IPP for the synthesis of sesquiterpenes, triterpenes, and phytosterols. However, the mevalonate pathway may be at least partly involved in taxane assembly. Virtually, all productive cultures of yew species are grown in dark (see below), indicating that the DXPS pathway is likely operating in proplastids or poorly differentiated chloroplasts, a scenario that is reinforced by the well established suppression of chloroplast differentiation and photosynthetic pathways by high sucrose levels used in culture media. The first committed step in the assembly of Taxol™ and related taxanes is the cyclization of the universal diterpenoid precursor geranylgeranyl diphosphate to taxa-4-(5), 11(12)-diene, a slow, but apparently not rate-limiting reaction, catalyzed by a diterpene cyclase (Fig. 3).

Cloning of the cDNA of taxadiene synthase in *T. brevifolia* by a homology-based PCR strategy revealed a 79-KDa peptide size and an N-terminal plastid transit peptide, in agreement with the plastid location of the diterpene biosynthesis. Heterologous expression of taxadiene synthase in bacteria followed by kinetic studies showed that, unlike several terpene synthases in plants, taxadiene synthase produces essentially one product and not multiple taxadiene isomers. The second specific step in taxane assembly involves the cytochrome P450-dependent hydroxylation at the C-5 position of the taxane skeleton, with allylic rearrangement, yielding taxa-4(20),11(12)-diene-5α-ol. This intermediate is acetylated at the hydroxyl in C-5 by an acetyl transferase to yield taxa-4(20),11(12)-dien-5α-yl acetate (Fig. 3). This is likely the third specific step in Taxol™ assembly and is responsible for generating the 4(20)-en-5α-acetoxy functional grouping from which the oxetane D-ring is established. A P450-dependent monooxygenase catalyzes the hydroxylation of the later molecule, resulting in taxa-4(20),11(12)-dien-5α-acetoxy-10β-ol. An additional cytochrome P450 cDNA clone encoding a product capable of hydroxylating taxadien-5α-ol at the C-13 position has also been identified.

The exact order of hydroxylation steps and the sequence of intermediates in the Taxol™ biosynthetic pathway are not clearly established, and it may be possible that various interconnected routes to this compound exist. The same applies to acylation reactions and the exact timing of epoxidation. After oxygenation, various hydroxylated positions in the taxane skeleton undergo esterification.

These acylation reactions appear to span early and later steps in the pathway. Whereas acetylation of the C-5 hydroxyl group occurs early in biosynthesis, acetylation at the C-10 hydroxyl and benzoylation at the C-2 hydroxyl take place later. Clones of cDNAs encoding these three taxane *o*-acyltransferases have been identified. The oxetane ring could arise by epoxidation of the 4(20)-double bond of the α-acetoxy group, followed by migration of

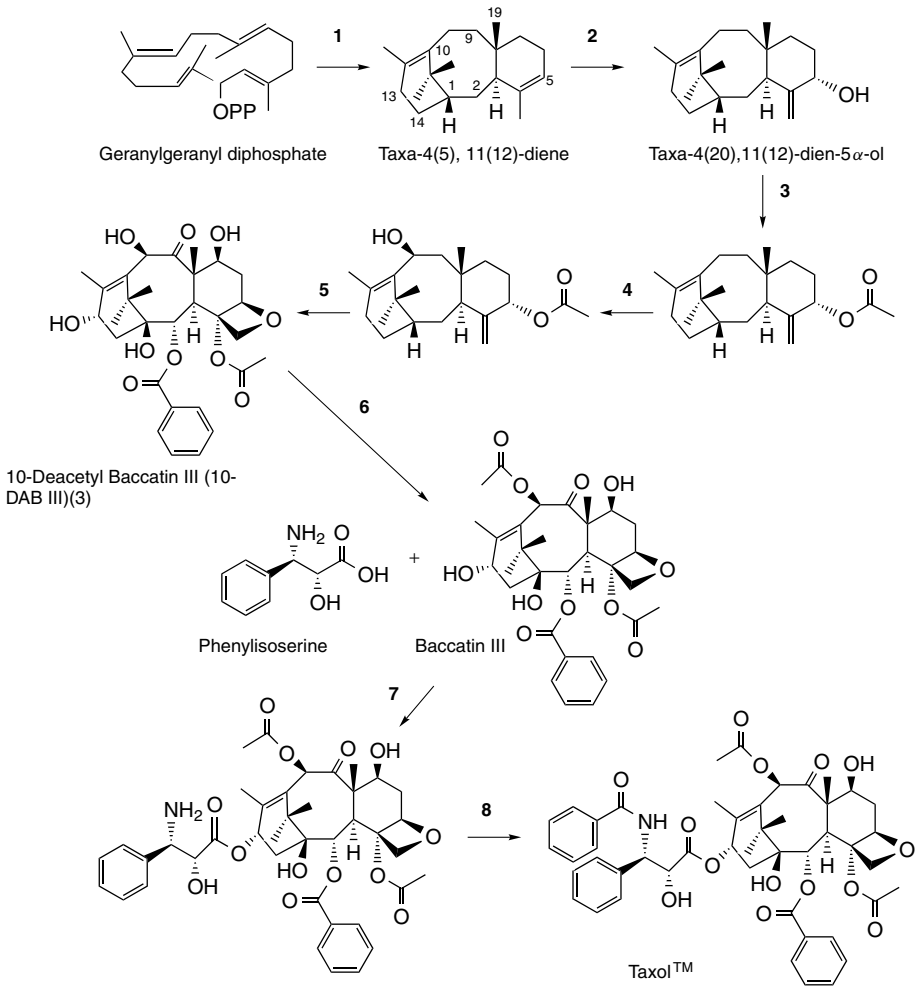

Fig. 3 A scheme of Taxol™ biosynthesis. **1**. Taxadiene synthase, **2**. Cytochrome P450 taxane-13α-hydroxylase, **3**. Taxa-4(20), 11(12)-dien-5α-*o*-acetyl transferase, **4**. Cytochrome P450 taxane-10β-hydroxylase, **5**. Multiple steps, **6**. 10-deacetyl baccatin III acetyl transferase, **7**. C-13 side chain addition, **8**. *N*-benzoylation.

the α-acetoxy group from C-5 to C-4, with oxirane-to-oxetane ring expansion. The attachment of the C-13 side chain to the taxane ring seems to involve initial esterification with phenylisoserine, followed by *N*-benzoylation. Phenylisoserine would be generated by an aminomutase reaction of phenylalanine to β-phenylalanine, followed by α-hydroxylation (Fig. 3).

5 General Characteristics of Taxol™ Yield and Growth in *Taxus* Cell Culture

This section focuses on the detailed analysis of a set of cell lines of *T. cuspidata* developed in the early and mid 90s at the University of Toronto to characterize the relationships and general features

of taxane production and cell growth. Early experiments with callus and cell cultures of *T. cuspidata* have shown that growth and Taxol™ yield are generally inversely proportional. The reason for this phenomenon, also observed with the production of other secondary metabolites by a number of plant species, is not well understood. Possible explanations include the lack of expression of key enzyme and/or transcriptional activator genes in cells with low differentiation, diversion of substrates for secondary metabolism into growth processes, unregulated catabolism, and lack of end product transport systems and storage sites.

The analysis of Taxol™ yields in different *in vitro* cultures of *T. cuspidata* supports the observation that faster growth rates and/or lower degrees of differentiation are normally associated with lower Taxol™ amounts. Stem-derived explants of *T. cuspidata* after two months of culture in B5bPVP displayed an average eight-fold increase in fresh weight and Taxol™ yields of $0.020 \pm 0.005\%$ of the extracted dry weight (equivalent to the yield of stems of the intact plant). Slow-growing, six-month-old immobilized cell cultures of *T. cuspidata* grown in B5C2 had variable amounts of Taxol™, up to $0.012 \pm 0.007\%$ of the dry weight (equivalent on average to the bark of the intact plant), whereas six-month-old immobilized cell cultures visually selected for faster growth yielded $0.0014 \pm 0.0003\%$ of Taxol™ on a dry weight basis. A two-year-old cell suspension line of *T. cuspidata* grown in B5C2 (dry weight doubling time of 17 days) yielded $0.0014 \pm 0.0005\%$ of Taxol™ (dry weight basis) when cultured as 300-mL suspensions in 1 L Erlenmeyer flasks. These yields may be altered by precursor feeding and various other strategies (see further sections).

Studies on the kinetics of growth and Taxol™ accumulation in cell suspensions of *T. cuspidata* (cell line FCL1F) showed a relatively slow growth rate and confirmed the relationship between growth and Taxol™ yield. The doubling time was approximately 17 days for fresh weight and 21 days for dry weight. Although relatively long in contrast to data from herbaceous species, these doubling times are comparable to or even shorter than those of other woody species that grow slowly (Table 2). The maximum specific growth rates were $0.040\ g^{-1}$ (fresh weight) and $0.034\ g^{-1}$ (dry weight). The accumulation of Taxol™ in the cells was not growth linked. The highest taxol accumulation values occurred in cells in stationary phase, and Taxol™ amounts in the cells decreased with the increase in cell biomass (Table 3).

Other taxanes in yew callus and cell cultures have been detected by HPLC, such as baccatin III, 10-deacetyl-baccatin III, 1-dehydroxybaccatin V, 7-epitaxol, and cephalomannine in both types of culture of *T. cuspidata*. Baccatin III yields in two-month-old callus of this species grown in B5bPVP were $0.043 \pm 0.016\%$ of the extracted dry weight. A two-year-old cell line suspension of *T. cuspidata* (FCL1) has been estimated to yield $0.018 \pm 0.010\%$ of baccatin III (extracted dry weight basis).

38	0.28	2.8	0.100
44	0.27	3.2	0.050

[a]Values are the mean of two to three determinations; inoculi were 1/6 w/v obtained from a single stationary phase donor suspension.
[b]EDW, estimated dry weight; nd, not determined; bd, below limit of detection.

Taxanes such as 10-deacetyl-baccatin III and baccatin III can be used to produce Taxol™ through semisynthesis. These taxanes can also be used to produce Taxotere™, a semisynthetic Taxol™ analog with higher antineoplastic properties and higher water solubility than Taxol™; Taxotere™ was first developed by P. Potier and associates and Rhône-Poulenc Rorer in France.

Media collected from six-month-old immobilized cell suspensions of *T. cuspidata* and extracted with dichloromethane may contain trace amounts of Taxol™ and baccatin III as indicated by HPLC analysis. In differentiated physiologically active cells, Taxol™ may be stored inside the cells, possibly in the vacuole or other membranous compartment. In a detailed time course study using the FCL1F cell suspension line of *T. cuspidata*, the analysis of the volumetric total production of Taxol™ at stationary phase indicated that 66% of the total Taxol™ was in the medium. In contrast, at a given time, Taxol™ accumulation in the medium on a per-milliliter basis was generally a small portion of that contained per gram of extracted dry weight basis in the cells (Table 3). The occurrence of a larger extracellular component of the total volumetric Taxol™ at stationary phase (productive phase) may be the result of excretion by the cells that reach highest amounts of Taxol™ accumulation in this phase. Studies on the production of various secondary products by plant cell cultures show that the proportion of excreted to endogenously accumulated product can be highly variable depending on species and cell line.

Taxol™ accumulation in the medium of cell suspensions of *T. cuspidata* can vary considerably with the time of the growth cycle. In the kinetic study just mentioned, the accumulation of Taxol™ in the medium had two peaks (Table 3). The first peak of Taxol™ in the medium ($\approx$0.4 µg mL^{-1}) occurred in the early portion of the exponential growth phase, soon after inoculation in fresh medium. This early release of Taxol™ in the medium could be a response to the transfer into fresh medium (''transfer effect'') and/or to the increase of the internal pH of the cells due to the absorption of ammonium (exchanged with H^-), which takes place in this portion of the growth cycle. Following the first peak, Taxol™ was degraded, possibly by enzymes released into the medium. A second peak of Taxol™ in the medium (0.1 µg mL^{-1}) occurred at stationary phase and may have resulted from excretion by the cells that reach their highest level of Taxol™ at this stage and/or from a small degree of cell lysis, common at later stages of the growth cycle. Baccatin III accumulation in the medium peaked after approximately nine days of culture at 6.2 µg mL^{-1} in the

same cell line suspension. The occurrence of product excretion into the medium is useful for industrial application of plant cell culture technology, since it facilitates downstream processing (especially when using immobilized cells).

From the mid-1990s on, a large research effort from various groups brought Taxol™ and taxane productivity levels in cell cultures to progressively higher values, in some cases reaching industrially interesting amounts. In the next section, different proven strategies to promote taxane yield in cell cultures are described.

6 Techniques to Improve Taxol™ Yield in Cell Culture

6.1 Precursor and Sugar Feeding

The problem of overall low Taxol™ yields, particularly at higher growth rates, can be partly overcome by feeding Taxol™ precursors to the cell cultures. The appropriate combination of type, amount, and feeding time of precursors able to enter the cells can significantly increase the yield of secondary metabolites in plant cell cultures, provided the biosynthesis of the metabolite of interest is at least partly limited by poor activity of enzymes involved in precursor formation or appropriate supply of precursor to the biosynthetic reaction. In two-month-old callus cultures of *T. cuspidata*, phenylalanine supplementation at 0.1 mM in B5bPVP can double the Taxol™ yield in relation to regular B5bPVP without affecting growth significantly; similar results can be obtained with cell suspensions after a 25-day growth period in medium supplemented with the same amount of this amino acid. Phenylalanine acts as a precursor for the side chain of Taxol™ and the benzoyl moiety at C-2.

Other potential precursors for the Taxol™ side chain were investigated in feeding experiments to both callus and cell suspension cultures of *T. cuspidata*. Compounds that significantly enhanced Taxol™ yields in cultures were phenylalanine, benzoic acid, hippuric acid, serine, and glycine. Impacts on Taxol™ yields were concentration dependent. Taxol™ yields were increased by two to four times when the putative precursors were provided at concentrations of 0.2 mM for callus cultures and 0.05 mM for cell suspension cultures; all cultures were fed at the onset of the stationary phase of growth. The best results were obtained with phenylalanine or benzoic acid feeding.

In a related approach, replacement of 2,4-D by Indole 3 acetic acid–glycine or Indole 3 acetic acid–phenylalanine conjugates yielded a two and threefold increase in Taxol™ production by cell cultures of *T. wallichiana* (Himalayan yew), respectively. Results suggest that precursor feeding is a promising approach to increase Taxol™ yields in yew cell cultures without detrimental effects on biomass generation.

Kinetic studies of taxane production in cell cultures showed that carbohydrate availability is closely related to biomass increase in *Taxus* cell cultures. Feeding of sucrose to *Taxus chinensis* cultures initially kept at 20 gL^{-1} and fed-batch system increased growth and taxane production; intermittent feeding of various concentrations of sucrose or maltose improved Taxol™ production in the same species.

An important aspect to consider is the osmotic effect of sugars on taxane production. It has been shown that high concentration of sucrose (60 gL^{-1}), combinations of sucrose and mannitol, as well as nonsugar osmotic agents

(polyethyleneglycol – PEG 4,000) were capable of improving Taxol™ yield in *T. chinensis* cell cultures. Cells cultivated in PEG-supplemented medium yielded a threefold increase of Taxol™ over the control. The authors have suggested that osmotic stress may improve secondary metabolism by directly modulating enzymes or by reducing growth rates and making more carbon available for secondary metabolism.

6.2 Cell Line Selection

Screening different cell lines for high yields of Taxol™ and/or taxanes may lead to the establishment and propagation of elite cell lines that can be used for large-scale production purposes. The technique has been successfully applied, for instance, to the production of ajmalicine by *C. roseus*, shikonin by *Lithospermum erythrorhizon*, and berberine by *Coptis japonica*. Although laborious and time-consuming, the approach may turn out to be advantageous for long-term potential industrial applications of yew cell cultures as a source of Taxol™ and taxanes.

The presence of a visual feature associated with high productivity is highly desirable for selecting high yielding cell lines (e.g. colored product, such as anthocyanin). In the case of *T. cuspidata*, additional studies are required to identify a reliable visual feature associated with taxane productivity. When such a facilitating screening parameter is not present at all, however, as it often happens, the use of standard phytochemical extraction and separation procedures is required or, if the product of interest can be made antigenic, immunoassays can be used in the screening procedure. Antitaxol and several other antitaxane antibodies are commercially available.

6.3 Light and Temperature

These physical parameters can be used to manipulate taxane production. The vast majority of protocols for yew cell cultures uses dark incubation. In a study on the effects of light on heterotrophic *T. cuspidata* cell suspension cultures and Taxol™ yield, it was established that white light of low intensity caused significant reduction in Taxol™ yield and growth; moreover, light-grown cells retained more intracellular Taxol™ and had much lower amounts of the taxane in the medium fraction (only 25% of Taxol™ was released to the medium versus 65% in dark-grown suspensions), presumably contributing to negative feedback of biosynthetic enzymes. Diversion of the phenylalanine pool from taxane biosynthesis toward synthesis of phenolic compounds in light-grown cells is another possible reason for light inhibition of taxol production. The effects of light have been shown to be the result of a direct effect of light on cell physiology and not photochemical degradation of medium components or taxanes, as judged from HPLC analysis of light-exposed Taxol™ solutions and growth performance in light irradiated versus control medium.

Temperature is generally maintained at approximately 25 °C for yew cell culture studies. A detailed investigation on suspensions of *T. chinensis* established that the optimum temperature for cell growth was 24 °C, whereas for Taxol™ production this parameter was 29 °C. By applying a strategy of temperature shift (from 24 to 29 °C) after a high cell biomass was achieved, a sustained higher Taxol™

production was obtained; whereas a reduction in the yield of the main taxane in this species, taxuyunnanine C, was observed. These results suggested that different branches of a metabolic pathway might have different optimal operating temperature conditions, and the temperature shifting strategy must be tailored to the specific target compound.

6.4 Elicitation and Metabolic Inhibitors

Elicitation is the stimulation of secondary product formation by specific compounds or physical conditions often mimicking environmental stresses. It has been successfully applied to improve Taxol™ yields in cell cultures. Jasmonate, a lipid-derived hormone, known as a signal molecule for herbivore and pathogen defense responses in plants, and related compounds have been used to induce taxane overproduction in *T. media, T. baccata and T. brevifolia* cell suspensions. Methyl jasmonate (MJ) added at 100 μM in medium at the time of cell inoculation has promoted Taxol™ and baccatin III accumulation to various extents (e.g. Taxol™ from 0.120 to 0.606% dw in *T. media* and 0.002 to 0.229% dw in *T. baccata*), with only moderate decreases in cell yield. Optimal configuration of MJ stereoisomers has been investigated to maximize taxane induction and minimize cell growth inhibition. A crude fungal extract of *Fusarium oxysporum* caused apoptosis in cells of *T. chinensis* var. *mairei*, as detected by microscopic and DNA analyses; Taxol™ yields tripled in treated cells.

Abiotic elicitors such as the heavy metals silver, cobalt, cerium, and lanthanium have also been used to stimulate taxane production in cell cultures. Enhanced Taxol™ production and release in *T. chinensis* cell cultures was obtained by a combination of ultrasound (US) treatment, MJ exposure and *in situ* solvent extraction (two-phase culture, see below). Ultrasound applied for 2 min once or twice during a four-week culture period increased volumetric Taxol™ yield 1.5- to 1.8-fold; MJ at 60 to 120 μM resulted in 5-fold increase, and *in situ* solvent extraction, 7- to 9-fold. The most effective combined approach was the application of US or MJ, followed by *in situ* solvent extraction, affording 33- to 35 mgL^{-1} of Taxol™, a 17-fold increase over control levels.

Suspension cultures are generally heterogeneous in the cell cycle phase of individual cells, which contribute to variable and relatively low magnitude production responses upon elicitation. Stable and optimized Taxol™ yields have been achieved in *T. chinensis* cultures by synchronization induced with phosphate starvation and low temperature treatment. Phosphate starvation was induced by transferring 15d old cells to phosphate-free medium for 25 days, followed by a second transfer to phosphate-free medium for additional 25 days. Low temperature treatment involved two cycles of 72 h exposure to 4 °C, each followed by transfer to 24 °C for 24 h. Synchronized cultures, particularly by low temperature treatment, doubled Taxol™ yields in response to elicitation with MJ relative to asynchronous cultures elicited in the same way.

Metabolic inhibitors have been examined as a means to divert resources from competing branch pathways towards the main pathway leading to the compound of interest. Since phenylalanine acts as a precursor to the phenylisoserine side chain of Taxol™ and the benzoyl moiety at C-2, attempts were made to inhibit the phenylpropanoid pathway at the level of phenylalanine ammonia lyase (PAL), expecting an increase in phenylalanine availability

for Taxol™ biosynthesis. However, the use of three different PAL inhibitors had little or inhibitory effect on Taxol™ yield, suggesting that more specific steps of the phenylpropanoid pathway need to be evaluated in order to achieve practical results.

Inhibitors have also been used to study the contribution of the mevalonate and 1-deoxy-D-xylulose (DXP) pathway to Taxol™ and baccatin III accumulation in *T. baccata* cell suspensions. Both mevinolin (inhibitor of the mevalonate branch, acting on HMG-CoA reductase) and fosfomidomycin (inhibitor of the DXP branch, acting on DXP reducto- isomerase) caused decreases in Taxol™ accumulation, whereas baccatin III was only reduced by fosfomidomycin. The results indicate that both pathways may be used for Taxol™ assembly with a predominance of the non-mevalonate one.

6.5 Gas Composition

The gas phase of flasks and bioreactors is often a determinant of secondary product accumulation. The effects of gas phase composition on Taxol™ was examined in shake-flask suspensions of *T. cuspidata*. Low head space oxygen (10% v/v) promoted early production of Taxol™, whereas high CO_2 (10% v/v) had an inhibitory effect. The same authors examined the role of ethylene, a gaseous phytohormone involved in various stress responses, in Taxol™ production. Gas composition also affected sugar, calcium, and phosphate uptake, which may have influenced taxane metabolism. The best combination for Taxol™ production was 10% (v/v) oxygen, 0.5% carbon dioxide, and 5 ppm ethylene. However, ethylene may have a dual effect on Taxol™ yield. In fungal elicitor-induced cell suspension of *T. chinensis* and *T. yunnanensis*, ethylene biosynthesis inhibitors (e.g. Co and Ni salts) and the ethylene action inhibitor $AgNO_3$ enhanced Taxol™ yield (up to threefold by combining Co and Ag); the opposite was observed with the ethylene-releasing compound ethrel. Such positive and negative effects were observed when adjuvants were added before or simultaneously with the elicitor, becoming progressively negligible when added 24 h after elicitation. Control of ethylene action and production during fungal elicitation appears to favor Taxol™ accumulation.

6.6 Protoplast Cultures

In general, protoplasts have not been used for useful metabolite production but as an important material for cell fusion and genetic transformation. One of the major advantages of using protoplasts is that the products are released freely into the broth with the double consequences of increasing overall productivity and facilitating down stream processing. Furthermore, since many high molecular weight substances (including elicitors) that are otherwise not accessible to the cells (due to the presence of cell wall) can directly access the cell membrane in protoplasts, the composition and concentrations of the metabolites produced by protoplasts may vary from those produced by cells. However, protoplasts are very fragile and cannot be used for long-term production process, and active protoplasts easily regenerate their cell walls during cultivation. In order to solve these problems, various gels were used as immobilization carriers (providing stability to the protoplasts) combined with an inhibitor of cell wall synthesis. Thus, active protoplasts were maintained for a long time without

cell wall regeneration. Immobilizing protoplasts is akin to providing them with an artificial cell wall. This concept has merits in that various useful functions can be freely incorporated in protoplasts by using artificial cell walls with such functions. Production of Taxol™ using *Taxus* protoplasts with artificial cell walls was feasible.

The optimal condition for isolating large amounts of viable protoplasts from *T. cuspidata* cultured cells was investigated. With a combination of cellulase, pectin lyase, polygalacturonase, hemicellulase, potassium citric acid buffer solution, bovine serum albumin (BSA), and potassium dextran sulfate and degassing treatments were found to be effective in increasing the yield of protoplasts isolated from *T. cuspidata* cultured cells. Protoplasts yields ($3.2–6.4 \times 10^6$ number/g-fresh weight cells) were achieved with specific culture and cell phases. This condition and these factors are thought to be useful for isolation of various *Taxus* species protoplasts.

The localization of Taxol™ in cultured *T. cuspidata* cells was investigated using protoplast isolation reaction. The amount of Taxol™ released by protoplasts isolation reaction was considered to be located in the cell wall and/or between cell wall (CW) and cell membrane. The amount of paclitaxel in the protoplasts was considered to be located in the cytoplasm. About 30% and 35% of total Taxol™ was located in CW of suspension cells in the growth phase and in the stationary phase, respectively (Table 1). It was also found that about 30% and 43% of total Taxol™ was located in CW of the cells grown in solid culture at growth phase and at the stationary phase, respectively (Table 4).

Since some of the Taxol™ is located in CW and the accumulation of Taxol™ in the medium was low, it was assumed that the cell wall limits the excretion of Taxol™ and that the amount of Taxol™ in CW may affect production of the same compound. It should be noted that Taxol™ production by *Taxus* cells is controlled by feedback inhibition due to the accumulation of Taxol™ in CW. Therefore we considered that the removal of cell walls would enhance Taxol™ production and developed a novel production system for isolated protoplasts. Figure 4 shows the Taxol™

Tab. 4 Localization of Taxol™ in *T. cuspidata* cells (1.0-g fresh weight) in suspension and solid cultures.

Phase	*Taxol™ in CW[a] [μg]*	*Taxol™ in cytoplasm [μg]*	*Ratio[b] [%]*
Suspension culture			
Growth phase (15 days)	6.6 ± 0.8	15.0 ± 1.4	30.5 ± 1.9
Stationary phase (22 days)	11.7 ± 0.8	21.6 ± 1.6	35.1 ± 1.0
Solid culture			
Growth phase (20 days)	9.9 ± 0.9	23.0 ± 2.2	30.1 ± 1.3
Stationary phase (35 days)	22.8 ± 0.8	30.0 ± 1.8	43.2 ± 1.4

[a] CW; cell wall and/or between cell wall and cell membrane.
[b] Ratio; [Taxol™ in CW/(Taxol™ in CW + Taxol™ in cytoplasm)] × 100.
Numbers represent mean value ± S.E.

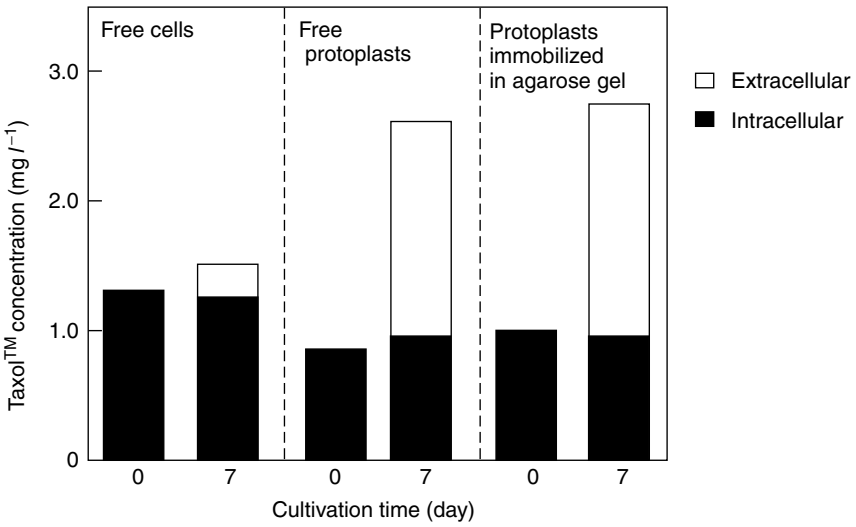

Fig. 4 Production of Taxol™ by *T. cuspidata* cells and free and immobilized protoplasts.

production by free cells and protoplasts in a static culture. Protoplasts produced a sixfold increase in Taxol™ in the medium compared to that of the free cells. In order to improve the stability of protoplasts, 3.0% agarose gel was used as the artificial cell wall material so that they could be cultivated by shaking culture without disruption. Agarose gel provided an artificial mechanical support to the protoplasts thus enabling them to withstand hydrodynamic stress. The protoplasts immobilized in agarose gel produced Taxol™ and released the compound into the medium as did protoplasts in static culture, yielding about six times more Taxol™ than free cells.

The system described here may be useful for the production of Taxol™ and other taxanes using different *Taxus* cell lines. Agarose was employed as an artificial cell wall and 2,6-dichlorobenzonitrile, for example, was used as inhibitor of cell wall synthesis. This system has merits in that various useful functions can be freely incorporated into protoplasts by using artificial cell walls with engineered functions. By using an appropriate artificial cell wall and an inhibitor of cell wall synthesis, it may be possible to further promote Taxol™ production. For example, Indole alkaloids production by *C. roseus* protoplasts was synergistically enhanced by using alginate gel as both elicitor and immobilization carrier, and $CaCl_2$ was used for both inhibitor of cell wall synthesis and signal transducer. Protoplasts with artificial cell walls have important potential applications.

The numerous approaches described above for enhancing taxane production in cell suspension cultures may be examined for Taxol™ production by protoplast cultures. Protoplast cultures provide a valuable tool for detailed study of biosynthetic pathways leading to efficient production of Taxol™. Furthermore, protoplast cultures represent a sustainable and relatively clean source of enzymes and genes involved in Taxol™ biosynthesis.

6.7 Culture System

Various culture systems have been tested for taxane production by cell cultures, both with free and immobilized cultures (glass fiber, alginate, etc.). Use of 50% conditioned medium instead of full replacement of medium has proven useful for the growth of *T. chinensis* and production of taxuyunnanine C. Two-phase culture systems involve the presence of a nonpolar phase to capture by partitioning the product of interest, thereby alleviating feedback inhibition on biosynthetic enzymes of cells in the aqueous phase. Product purification is also facilitated in this system. Accumulation sites for compounds of interest of the solid resin type (e.g. Amberlite XAD series) have promoted Taxol™ yield in *T. cuspidata* by 40 to 70%.

Organic solvents used in two-phase culture systems have also been used for taxane production in cell cultures; application of 10 to 11% (v/v) dibutylphthalate as the *in situ* solvent extraction has improved Taxol™ with minimal deleterious effects on cell growth and integrity.

Two-stage cultivation, involving a growth and a production medium, has been largely used for taxane production in cell cultures. The most frequent strategy involves addition of precursors and elicitors or the exposure to abiotic factors (such as temperature shifts) after a certain cell biomass has been attained.

Semicontinuous and perfusion cultures, which involve medium replacement throughout the growth cycle, have been used for Taxol™ production studies. In *T. canadensis*, a fourfold increase in accumulation was observed in semicontinuous cultivation with total cell recycle versus batch culture. Alginate immobilized cultures and free cells with a nylon-mesh separator of *T. cuspidata* were cultivated in continuous medium perfusion mode and resulted in an order of magnitude higher Taxol™ specific production (0.3 mg gdw^{-1} day^{-1} for 40 days) relative to batch cultivation; however, some degree of cell growth inhibition owing to a dilution effect was observed.

7 Scale-up of Taxus Cell Cultures

The scale-up of plant cell cultures remains a challenge in spite of considerable efforts to bring this technology to commercially viable use. In general, as culture systems move from flask to bioreactor and further up to large-scale cultivation, productivity and growth drop considerably. Problems during scale up include shear stress, control of gas composition, lack of adequate mixing of medium and cells, and oxygen supply. Yew cell cultures have been cultivated in bioreactors, in a large scale, to a significant degree of success compared to other species capable of accumulating industrially interesting chemicals.

The general strategy used for scale up cultivation of yew cell cultures has been to combine some of the above-described techniques and adapt their application to the reactor setting to improve yields. Some examples of bioreactor cultures of yew species are depicted in Table 5. Taxol™ from cell culture–based large-scale production has been commercialized since 2001 by Samyang Genex (Taejon, Korea).

8 Future Perspectives

Data to date shows that cultured cells of *Taxus* spp. represent a viable source

Tab. 5 Examples of bioreactor production of taxanes to industrially significant amounts.

Species	*Equipment*	*Taxane*	*Production [mg L^{-1}]*	*Productivity [mg L^{-1} × d]*	*Treatment*
Taxus media	Stirred reactor, 5 L capacity	Taxol™	21.1	1.06	Methyl jasmonate, Precursor feeding, 2-stage media
		Baccatin III	56.0	2.8	
T. cuspidata	Baloon (bubble reactor), 20 to 500 L	Total taxanes	74	2.74	Feeding or medium replacement
T. chinensis	Bubble column, 1 L	Taxuyunnanine C	229	13.5	Ethylene addition
	Airlift, 1 L	Taxuyunnanine C	336	20.2	Methyl jasmonate, ethylene addition and sucrose feeding
	Airlift, 1 L	Taxuyunnanine C	612	24.7	Repeated methyl jasmonate application and sucrose feeding

of Taxol™ and related taxanes, which can be used in the production and semisynthesis of this antineoplastic agent and its analogs. Scaled-up cell cultures and alternate modes of taxane production, such as protoplasts and perfusion culture systems need to be further developed by combining the knowledge that has been successfully applied to suspension cultures with the particular features of these culture methods.

The molecular characterization of taxane biosynthetic genes, the availability of their sequences, and protein products expressed in microorganisms for detailed kinetic studies open important perspectives for the establishment of engineered yew cell cultures transformed with genes controlling slow or limiting biosynthetic steps driven by strong or easily inducible promoter sequences. The knowledge of cis elements in promoter sequences of taxane biosynthetic genes may shed light on their modes of regulation and contribute to their efficient manipulation. Alternatively, antisense transformation or the use of RNA interference techniques may be useful for the suppression or inhibition of competing pathways, making more carbon, nitrogen, and energy flux available for relevant taxane assembly. In that regard, the recently observed preferential induction of C-13 oxygenated taxanes (more pharmaceutically relevant) by MJ in *T. media* cell cultures points to taxoid 14β-hydroxylase, a recently cloned cytochrome P450-dependent monooxygenase, as an interesting target for inhibition in cultures that produce C-14 oxygenated taxanes. As the molecular basis of taxane biosynthesis if further detailed, the identification of trans-activating factors (DNA binding proteins) controlling the coordinated expression of multiple biosynthetic genes

may allow for more efficient and rational control of the metabolic flux toward specific taxanes of interest. Genetically engineering cell cultures with these ''master'' regulatory genes may facilitate the control of the complex pathways leading to Taxol™ and related taxanes. Interestingly, recent progress has been made in the control of the pathways leading to monoterpene indole alkaloids in *C. roseus* by genetically modifying the expression of the ORCA family of transcription factors, which regulate the expression of biosynthetic genes involved in the indolic portion of the pathway and which are activated by jasmonate and related compounds. Since taxane biosynthesis is also strongly induced by jasmonate, it is possible that homologs of these transcription factors operate in yew species. Other potential targets for genetic modification in yew cell cultures include gene products responsible for taxane transport in and out of cells and between subcellular compartments.

The continued analysis and characterization of new taxanes produced in cell cultures may directly yield or provide leads to the development of pharmaceutically more efficient Taxol™ analogs. Moreover, new and important bioactivities may be uncovered from the vast chemical array of taxanes.

Keywords

Steroid Hormones
Lipophilic hormones (lipid-soluble) which derive from cholesterol and act through association with their cognate receptors (specific nuclear receptors for each class of hormones, i.e. estrogens, androgens, progestins, gluco- and mineralocorticoids).

Nuclear Receptor
Large family of ligand-dependent transcription factors (peptides able to modulate the expression of genes).

Targeting
Modality to selectively deliver a compound to a given cell type or tissue to produce a biological effect only at his level.

1 Background

Steroid hormones once secreted are transported through the blood by proteins such as albumin or sex hormone binding globulin to be delivered to specific receptors located in various tissues, including tumors. Hence, steroid hormones appear as attractive vectors that might be used to achieve a selective targeting of anti-neoplastic drugs, at least in hormone-dependent cancer, which contains high amounts of receptors (i.e. breast, prostate etc.). While association of these drugs with receptors is obviously of major importance, their binding ability to transport proteins may also play a role (i.e. albumin localize at the tumor due to enhanced vascular permeability).

Such a concept is obviously not new. High doses of steroid hormones are indeed routinely used for the treatment of various endocrine disorders. Synthetic antagonists aimed to specifically block the action of their receptors or/and metabolic enzymes have also been in clinical practice since a long time. With specific regard to neoplasia, antiestrogens, antiprogestins, as well as aromatase inhibitors (enzymes that convert androgens to estrogens) are drugs of prominent importance for the treatment of breast cancer. Therapeutic effectiveness as well as mechanism of action of such compounds has been the subject of a large number of reviews and will therefore not be addressed here. Potential utility of steroidal derivatives aimed to selectively kill tumor cells (i.e. ''antitumor steroids'') will solely be analyzed.

In fact, during the last 30 years, several investigators prepared a large number of steroids bearing cytotoxic molecules (e.g. alkylating agents, nitrosoureas, *cis*-platinum complexes, intercalating agents, etc.). Unfortunately, such syntheses led almost always to drugs devoid of therapeutic interest primarily due to the fact that their cytotoxic groups were not linked in appropriate positions onto the steroids, leading to a drastic loss of the binding affinity of the latter for their cognate receptors with concomitant decrease of cellular uptake. Moreover, for the few compounds that overpass this limiting step, specific killing of tumor cells was rarely observed in cell culture

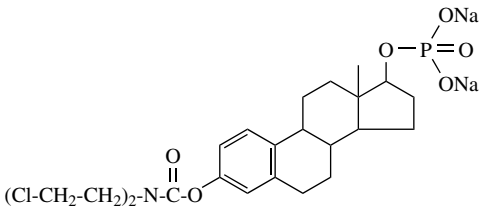

Fig. 1 Chemical formula of estramustine phosphate (Estracyt).

(receptor-positive vs receptor-negative cell lines) precluding their potential testing in clinical trials. Metabolistic instability of compounds also precludes their use. In fact, out of the hundreds of compounds synthesized, estramustine phosphate (Estracyt) (Fig. 1) is the only one having a place in the therapeutic arsenal (treatment of advanced prostatic cancer).

The growing number of experimentally determined crystal structures of ligand-binding domains of steroid hormone receptors provided a theoretical basis for the synthesis of a new generation of cytotoxic-linked steroids having a chance to associate with their cognate receptor. It is our purpose to focus on this topic. First, we will rapidly describe the structural determinants that govern the interactions of a ligand with its receptor, with special emphasis on estrogens and antiestrogens. Major advances in the synthesis of cytotoxic-linked estrogens in comparison with other classes of steroids justify this option. Next, we will move to the description of estrogen derivatives with potential antitumor activity.

2
Steroid Hormone Receptors

2.1
Structure and Conformation of the Hormone Binding Domains

Steroid hormone receptors are members of a superfamily of nuclear receptors, which regulate the expression of gene involved in cell proliferation and/or differentiation. All these receptors encode various domains with specific functions (A/B, C, D, E, and F; Fig. 2). The N-terminal A/B domain of each receptor contains a ligand-independent activation function (AF-1) required for the transcriptional activation of target genes. The adjacent C-domain contains two zinc fingers, which play an important role in DNA sequence-specific bindings (association with specific response elements). The D-domain is a hinge region, which separates ABC domains from the hormone binding domain (HBD; domain E). This binding domain contains a ligand-dependent activation function (AF-2) located in its carboxy-terminal part, a third additional AF-site located on the amino-terminal part of the HBD has been reported in the gluco and estrogen receptors (AF-2b). The C-terminal part of the receptors (end of domain E and F) is involved in the regulation of their half-life (proteolysis) and transcriptional activity.

Binding of a steroidal hormone to its receptor always provokes a conformational change in the latter that allows, ultimately, the transcription of target genes. Receptor molecules, in homo- and heterodimeric associations, exert their transcriptional effect through interaction with response elements located in the promoter region of these genes; alternatively, they may operate via their interaction with other classes of DNA-bound transcription factors (i.e. AP1,

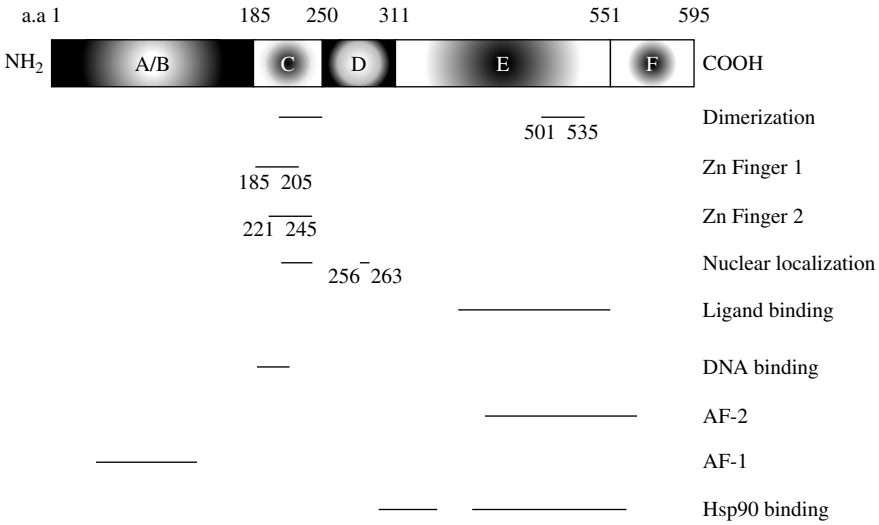

Fig. 2 ERα domains. ERα is composed of six molecular domains, which allow it to localize into the nucleus, dimerize, bind to ligand and DNA, and regulate the transcription through hormone-independent (AF-1) and hormone-dependent (AF-2) mechanisms.

Sp1 etc.). Transcription requires nuclear proteins (coactivators) that are recruited by the DNA-bound receptors. Coactivators vary among tissues eventually giving rise to tissue-specific responses to a given hormonal stimulation. Antagonists repress transcription by a reverse process (blockade of association with response elements and/or recruitment of corepressors).

AF1 expression is regulated by growth factors via classical signal transduction cascades while AF2 (and apparently AF-2b) is entirely dependent on the association of the receptor with the ligand. Under most conditions, the ligand induces a functional synergism between AF1 and AF2 due to major reorganization in the tertiary structure of the receptor. HBD contains 12α-helixes (H1–H12) folded into a 3-layered antiparallel α-helical sandwich. The central core of the HBD layer contains 3α-helixes (H5/6, H9, and H10) sandwiched between 2 additional layers of helixes composed of H1–4, H7, H8, and H11; it is flanked by H12, which contains the core region of AF2. Agonists elicit a receptor conformation of the HBD so that H12 is aligned over the hormone binding cavity; the formation of a salt bridge between H4 and H12 stabilizes the reposition of the latter. This main conformational change results in the emergence of a specific binding site (a groove) for a consensus α-helical motif (LxxLL, ''NR'' box) found in coactivators. Antagonists sterically interfere with H12 positioning thereby preventing recruitment of coactivators and favoring binding of corepressors.

2.2 Conformational Changes of Ligand-binding Domains Induced by Agonists or Antagonists

HBD structure of each steroidal hormone receptor has been established by amino acid labeling with reactive ligands,

site-directed mutageneses, hydrophobic cluster analyses, motif-based searches for homology with other proteins of known structures, and crystallographic studies. All HBDs are hydrophobic pockets, except at subsites corresponding to polar centers of cognate hormones; virtually, amino acids of these binding pockets surround the steroids. HBDs are somehow flexible in order to accommodate various ligands. Enlargement of a subsite results from the conformational reorganization of the whole HBD upon ligand binding: occupation of one subsite may modify the flexibility at a second subsite indicating that they respond to the ligand as a whole entity. Subsites are flexible because HBDs are composed of polypeptide segments rich in amino acid residues with mobile side chains (e.g. lysine, methionine, etc.).

Interaction of a steroidal hormone (or any synthetic ligand) with its cognate receptor depends upon several parameters (size, shape, polarity of atoms within the steroidal rings, etc.). Polar functions located at the extremities of the steroidal core (pos. 3 et 17) are of prominent importance for the onset of a biological function, as illustrated hereunder by the binding of estradiol (E_2) and the partial antiestrogen hydroxytamoxifen (OH-Tam) to the estrogen receptor (α-isoform).

Most important amino acids involved in the binding of E_2 to the ER-HBD are Glu353 and Arg394 on the one hand, His524 on the other hand: Glu353 and Arg394 interact with the C_3 phenolic group of the hormone (H-bridge, participation of an H_2O molecule) while His524 interacts with 17β oxygen (Fig. 3). As stated above, location of E_2 within the HBD leads to a displacement of H12 favoring the access of coactivators to their binding site; virtually H12 surrounds E_2 and shields the pocket where it is locked from the environment (''closed conformation'').

OH-Tam (Fig. 4) is a triphenylethylenic derivative of prominent importance for the treatment of ER-positive breast cancer; aminoalkyl side chain of the compound is responsible for its antiestrogenic (and cytostatic/cytotoxic) activity. Phenolic group of the drug (pos. 4) interacts with Glu353 and Arg394, as the C_3 phenolic group of E_2.

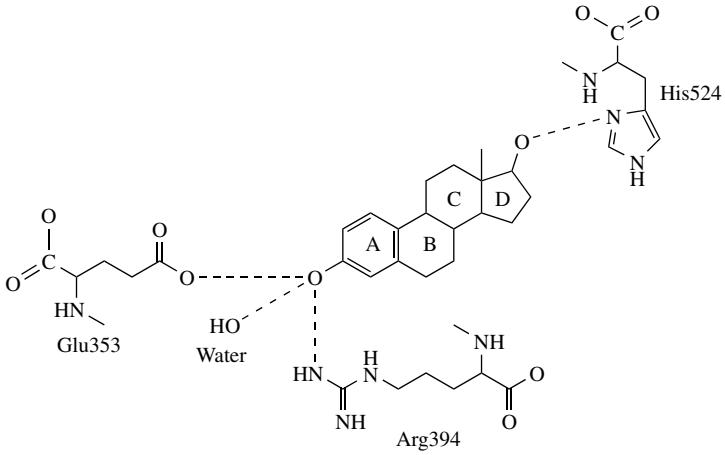

Fig. 3 Docking of E_2 in the ERα-HBD. The phenolic A-ring of E_2 is located in the HBD by Glu353 and Arg394 and tethered by His524.

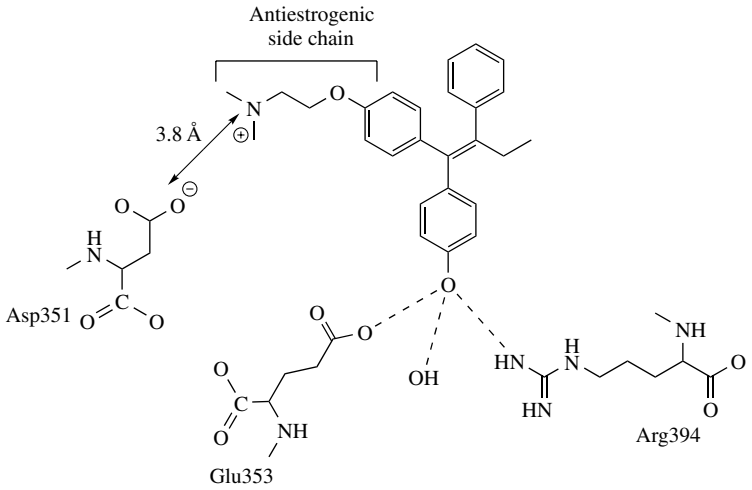

Fig. 4 Docking of OH-Tam (partial antiestrogen) in the ERα-HBD. The phenolic ring of OH-Tam is located in the HBD by Glu353 and Arg394, in analogy with the A-ring of E_2 (see Fig. 3). The nitrogen atom of the amino alkyl side chain of OH-Tam weakly interacts with Asp351. This interaction seems to be the key to the antagonistic activity of the compound.

However, in the hormone binding pocket, binding of OH-Tam to ER promotes a conformational change differing from that driven by E_2 inasmuch as the orientation of H12 appears essentially different. In the OH-Tam–ER complex, H12 is oriented in such a way that it maintains the pocket wide open, allowing the specific interaction of the nitrogen atom of the side chain of OH-Tam with a residue of the binding pocket (Asp351). In this ''open conformation'', which is stabilized by the side chain of the antiestrogen, H12 occupies a part of a coactivator binding site, which normally becomes accessible upon E_2 exposure. As a consequence, OH-Tam-associated H12 reorientation abrogates the recruitment of coactivators perhaps in favor of corepressors (AF-2 silencing). Hence, interaction between the side chain of OH-Tam and Asp351 seems to be the key to the antagonistic activity of the compound. Note that this open conformation of the HBD allows the expression of other transcriptional activating sites (AF-1 and to some extent AF-2b) explaining the partial estrogenicity of OH-Tam.

OH-Tam belongs to an important class of clinically relevant compounds, recognized now as *selective estrogen receptor modulators* (SERMs). These compounds act as antagonists or agonists, depending on the cellular type promoters and coregulators (ER isoform is also of importance). A second class of antagonists, (ICI 182,780, ICI 164,384 and RU 58,668; Fig. 5) are capable of completely blocking the transcriptional activity of ER via the inhibition of both AF1 and AF2 action. One may speculate that these ''pure antiestrogens'' could play an important role as a second-line therapy against advanced breast cancer in patients who develop resistance to tamoxifen treatment. They correspond to 7α or 11β derivatives of E_2 in which specific reactive groups are linked to the steroidal moiety

Fig. 5 Chemical formulas of pure antiestrogens.

through a long alkyl side chain intended to protrude out of the HBD when bound to the receptor (as the side chain of OH-Tam and related SERMs). The resulting conformational state of the receptor is, however, slightly different from that elicited by all investigated SERMs, although their long alkyl side chain similarly abrogate the alignment of H-12 onto the steroidal core.

3 Restrictive Conditions for Efficient Targeting of Antitumor Estrogens

To utilize steroid hormones as effective delivery vector of cytotoxic drugs to the tumor cells, several conditions should be satisfied. Concerning the association of the compounds with their receptors, we stress the need for the following four conditions:

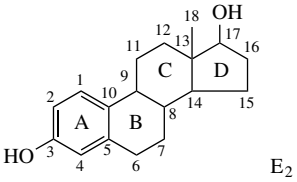
1. It is important to link the cytotoxic agent in such a way as to not interfere with the recognition of the steroidal vector.
2. The cytotoxic moiety should be shipped to its target. Since receptors focalize their action at the genomic level, drugs to be linked to the steroid are restricted to those producing damage at the DNA level or associated nuclear proteins.

3. The compounds should not produce a rapid loss of binding ability of their steroidal vector.
4. The concentration of receptors should be sufficiently high to produce an effective cellular uptake of the cytotoxic moiety. This concentration should be maintained until this cytotoxic moiety has reached its target, potential degradation of the receptor (downregulation) induced by the steroidal vector should be limited.

The following paragraphs analyze how such conditions could be satisfied for (anti)estrogenic conjugates.

3.1 Main Structural Requirements for Estradiol Binding

The main and unique characteristic of E_2 is its lack of binding affinity for steroid hormone receptors other than its own receptor. The phenolic group in C_3, not recorded in the other steroid hormone, generates this big difference. Binding data of E_2 and derivatives led to the following conclusions.



E_2

3.1.1 A-ring

C_1 is intolerant of both hydrophobic and polar substituents, suggesting close contacts with the HBD. The hydroxy group in C_3 donates a proton to Glu353 and Arg394 (see above), and this bond is donated *syn* to the C_2-C_3 bond. C_4 may be in close proximity to a cysteine residue, based on inactivation assays of the receptor by 4-mercuri-E_2. The A-ring electron cloud may be engaged in a weak polar interaction with a slightly positively charged receptor residue, situated on the β-face of the steroid.

3.1.2 B-ring

C_6 seems to be intolerant for both polar and nonpolar substituents, once again suggesting close interaction of this area to the receptor essential spatial volume. Large aliphatic chains at $C_{7\alpha}$ are well tolerated (i.e. pure antiestrogens ICI 164,384 and ICI 182,780; Fig. 5), they localize within a subsite of the HBD accepting 11β nonpolar substituents (rotation of the E_2 core around a virtual symmetry axis that runs roughly through C_3 and C_{17}). Positions in $C_{7\beta}$ and $C_{8\alpha}$ are unexplored and $C_{9\alpha}$ has low steric tolerance.

3.1.3 C-ring

A preformed hydrophobic subsite of the HBD has a high steric tolerance for 11β residues. It can accommodate aromatic substituents bearing aliphatic side chains (pure antiestrogen RU 58,668; Fig. 5) while still retaining high affinity; it is intolerant of polar groups. The covalent binding of tamoxifen aziridine has suggested an accessible receptor nucleophile in $C_{11\beta}$ vicinity; such a hypothesis was rejected since 11β-methyl aziridine estradiol does not covalently label ER. Moreover, 11β-chloromethyl and bromoacetyl analogs also fail to covalently label the receptor. The 11β-chloromethyl substituent of E_2 produces, however, a *quasi*-irreversible binding of the hormone with the receptor. Interaction of the chloride atom with a putative

Zn^{++} ion located within the receptor has been proposed to explain this extremely high binding affinity; hydrophobic interaction with a tryptophane or phenylalanine has been advocated as an alternative hypothesis. The 12β-site accommodates small nonpolar groups as methyl; otherwise, C_{12} has been scarcely investigated.

3.1.4 D-ring

C_{14} can accept small, nonpolar groups at the α- or β-sites without appreciable loss of binding affinity. C_{15} is intolerant of small hydrophobic substituents (methyl) or replacement with oxygen. $C_{16\alpha}$ accommodates large nonpolar groups (e.g. iodine), but $C_{16\beta}$ is sterically less accessible, and even fluorine substitution decreases the binding affinity substantially. ER accepts small nonpolar groups in $C_{17\alpha}$ or groups in which the extended bulk should be directed in an endo manner, for example, *Z*−CH=CHI binds more effectively than the corresponding *E*-isomer. Spatial tolerances of this area are precise, because even an ethyl group at this position results in significant loss of binding affinity; this effect may be secondary to alteration of rotation of the 17β-hydroxyl group. The 17β-hydroxyl group acts as a H-bond acceptor from His524. There may be a lysine and two cysteine residues (one positioned on each face of the steroid) in the vicinity of C_{15}-C_{16}-C_{17}, based on the reactivity of E_2 derivatives bearing covalently labeling groups. The 18-methyl group is not a significant contributor to binding, indicating no productive contact with the receptor at this site.

Data summarized here define localizations for grafting of a cytotoxic compound onto estradiol.

1. Positions 7α and 11β appear especially appropriate for large substituents without provoking a dramatic loss of binding affinity. In fact, this has been proved by linkage of a porphyrin in position 11β through a side chain. Linkage on 7α or 11β would localize the substituent within the same region of the receptor: the steroid may indeed rotate around a virtual symmetry axis between C_3 and C_{17}. Hence, 7α and 11β seem quite equivalent for grafting a side chain bearing a cytotoxic compound. Flexibility of such chains does not appear of prime importance as revealed by the study of mobile $[(CH_2)_n]$ or inflexible $[(CF_2)_n]$ spacers.
2. Substitution in 17α may also be recommended, provided that a short spacer is introduced between E_2 and the cytotoxic compound to maintain an effective binding affinity. Ethynyl and vinyl groups are especially accurate since they give an effective separation without excessive conformational flexibility. Directing these substituents away from the β-face of the steroid (side of the 17 OH) is required to limit steric interference with the binding pocket.

3.2 Nucleocytoplasmic Shuttle of Estrogen Receptors

Nuclear receptors are ''translocating binding proteins,'' which continuously move between the cytoplasm and the cell nucleus (shuttling mechanism). The nuclear localization, however, always dominates especially under agonist stimulation (a dynamic event resulting from the continuous active transport of the receptor into the nucleus, slightly counterbalanced by its diffusion into the cytoplasm). Receptor detection in the cytosol of extracts

from unstimulated cells may derive from its nuclear release at the time of homogenization.

Conveyance of ER into the cell nucleus is governed by specific amino acid sequences and nuclear localization signals (NLSs) situated between its DNA and hormone binding domains (HBDs) (hinge region). The existence of nuclear export signals (NESs) has also been reported; both NESs and NLSs play an important role in nuclear export of the steroid receptors. Nuclear uptake of receptors requires ATP, while nuclear export apparently occurs in the absence of energy production.

Investigations performed on ER-transfected cells revealed an additional subnuclear movement of the receptor under ligand stimulations. E_2 changes the receptor pattern from a diffuse nucleoplasmic aspect to a hyper-speckled distribution, suggesting that the ligand-dependent organization of the receptors within the nuclear matrix involves more complex events than a simple recognition of DNA-binding sites and coregulators. Interestingly, such a hyper-speckled distribution also occurs with the partial antiestrogen OH-Tam, while a substantial effect is solely detected with the pure antagonist ICI 182,780. In this context, it should be stressed that several other investigations localize the receptor within the cytoplasm under exposure to pure antiestrogens. Hence, the cellular localization of the receptor under pure antiestrogens is still not established, although the tendency for a major distribution within the cytoplasm dominates (when downregulation does not occur, see Sect. 3.4).

Concepts outlined here suggest that linkage of cytotoxic residues aimed at altering DNA and associated proteins should be restricted to estrogens (and SERM), pure antiestrogen having only a chance to strongly associate to the nuclear matrix.

3.3 Ligand-induced Regulation of Estrogen Binding Capacity

Shuttling of ER between the cytoplasm and the nucleus influences its ligand-binding ability. The nuclear localization of a receptor is associated with a loss of ligand-binding ability, which is restored by its return into the cytoplasm (dephosphorylation/phosphorylation cycle). After several cycles, ER is degraded by the proteasomal pathway, most probably into the cytoplasm (half-life 3 ~ 4 h); ubiquitination of the receptor favors its shipment to the proteasome. Inhibitors of protein synthesis (cyclohexamide, puromycin) interfere with this mechanism leading to a stabilization of the receptor within the cell nucleus in a form devoid of strong ligand-binding ability.

As stated above (Sect. 2.2), E_2 is stably incorporated within the HBD, decreasing the chance of exchange with unbound ligands (closing of the binding pocket). Such a property fixes the majority of the receptor molecules into a conformation appropriate for a specific anchorage within the cell nucleus (hyper-specked pattern) to accomplish functions imposed by the hormone. A progressive decrease of estrogen binding capacity subsequently occurs. As expected, this decrease is closely related to the binding affinity of the estrogen for the receptor, which is a major determinant of its nuclear stabilization. One may anticipate that this receptor form, unable to bind the hormone is subjected to a return into the cytoplasm to be recycled or degraded.

Partial antiestrogens (OH-Tam and related SERMs), which maintain the HBD in an open conformation, accumulate the receptor within the nucleus in which it progressively loses its ability to bind estradiol. Blockade of the proteasomal degradation of ER by these antagonists associated with maintenance of its synthesis (see Sect. 3.4), explains this accumulation process.

3.4 Ligand-induced Regulation of Estrogen Receptor Level

Ligands strongly influence the turnover rate of ER, by regulating its production and ubiquitin-dependent proteolysis. Estrogens block ER synthesis (decrease of ER mRNA level) while antiestrogens do not. Maintenance of ER synthesis under antiestrogen treatment may therefore upregulate the receptor when its proteasomal degradation is weak, as observed with OH-Tam and related SERMs. Estrogens and pure antiestrogens induce a strong and rapid ubiquitination of the receptor, leading to its rapid proteolysis; SERMs are largely less effective in this regard. As a consequence of these regulatory processes, estrogens, and pure antiestrogens downregulate the receptor while SERMs may lead to its accumulation.

The ability of cycloheximide and puromycin to stabilize the activated receptor within the cell nucleus suggests the induction of a protein favoring its return into the cytoplasm where it would be degraded. This concept of cytoplasmic degradation is supported by the observation that cycloheximide and puromycin fail to block the ER elimination when it is provoked by pure antiestrogens, which fail to stabilize the receptor within the nucleus.

In fact, only 10% of ER molecules should be saturated by a ligand to produce the proteasomal degradation of the whole population. Moreover, receptors of which the HBD has been blocked by a covalent binding (i.e. tamoxifen aziridine) are similarly eliminated. The mechanism underlying this amplification process is not known. Secretion of unidentified hydrophobic compounds by early-stimulated cells may play a role. Such compounds, the existence of which has been detected in conditioned media from ligand-treated cells, may act by themselves or in synergy with undetectable concentration of ligands.

4 Antitumor Estrogens

ER content is extremely variable among breast cancer. Median concentrations vary among studies reaching a maximum of 100 fmoles mg^{-1} proteins, which correspond roughly to 10 000 receptors per cell. Only a limited number of cytotoxic drugs would be able to exert significant antitumor effect with such a low concentration of vectors. The high reactivity of alkylating agents (1000 DNA interstrand cross-links is lethal) led to their selection for the synthesis of antitumor estrogens. Numerous compounds were synthesized in the 1970s and 1980s. However, as stated above, most of them failed to display a sufficient binding affinity for ER, or any unambiguous specificity of action, leading to a progressive disinterest to this approach. Other cytotoxic agents such as vinca alkaloids and intercalating agents (like ellipticin and daumomycin) also failed to show any potential therapeutic interest. Note that

this remark also holds for nonsteroidal cytotoxic derivatives (i.e. diphenyl and triphenylethylene (anti)estrogens).

In the following years, accumulation of data concerning the receptor's structure, binding requirement, and mode of action (previous sections) dictated new guidelines for syntheses. Research axes of the last decade are overviewed in the following paragraphs.

4.1 Organometallic Estradiol Derivatives

The advance in organometallic chemistry associated with the discovery of the antitumor activity of cisplatin led to the analysis of the potential use of metal-conjugated estrogens. Since cisplatin is unsuitable for breast cancer treatment, the search concentrates mainly on non-platinum metal complexes such as cyclopentadienyl cycles of Ru, Ti, Fe, Co, and so on, which appear attractive in cancer chemotherapy. Nonetheless, cisplatin was also linked with the hope of extending its therapeutic use. While DNA is the expected target of such drugs, some of them were found to irreversibly associate with the receptor, a behavior that may produce unusual biological properties.

Unfortunately, endocrine and therapeutic activity of most of the metal-conjugated estrogens has not yet been explored. Investigations mainly concern their binding to the receptor. The effect of ER-positive and ER-negative cell lines has been assessed in only a few cases.

4.1.1 A-ring Complexion

An important feature displayed by organometallic clusters is the possibility of their complexion on either the α- or β-side of the steroid A-ring (Fig. 6). Studies conducted with chromium and ruthenium complexes reveal that a π-organometallic adduct on the β-face prevents the binding of E_2 to the receptor while its addition on the α-face maintains some binding affinity. Of these compounds, the neutral chromium complex displayed the highest binding affinity ($\sim$30% of E_2). Although the cationic species Cp^*Ru^+ failed to seriously alter the binding of the hormone, as demonstrated

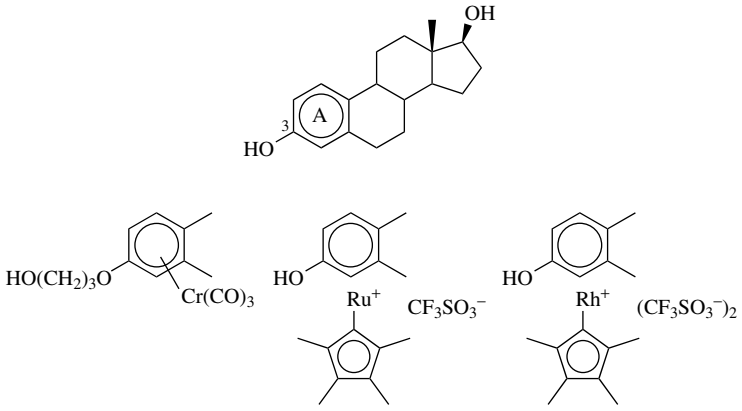


Fig. 6 Organometallic E_2 derivatives – chemical formulas of A-ring substituted derivatives described in Sect. 4.1.1. Binding affinity for ER of the organometallic abduct is higher on the α face of A-ring those on its β face.

by α-[Cp*Ru(17β-estradiol)][CF_3SO_3], an increase in the positive charge of the organic moeity (i.e. Rh^{++}) appears detrimental. This effect may be attributed to an increase in acidity; the complexion of the phenolic A-ring increases its acidity. In a basic medium, the complexed phenolic rings are transformed into the corresponding dienonylic rings with the concomitant loss of 3-OH function required for strong association with the receptor.

4.1.2 7α and 11β Derivatives

Grafting of organometallic clusters in these strategic regions is expected to be relatively well tolerated (Sect. 3.1). Hence, various compounds have been synthesized.

Nonradioactive Re systems are analogous to corresponding nonradioactive systems containing ^{99m}Tc, ^{186}Re or ^{188}Re. For this reason, they may be viewed as prototypes for the production of drugs to be used in imaging and radiotherapy. Attempts to produce 7α derivatives in which the rhenium moeity is remote from E_2 by a long side chain led to the identification of a few compounds with high binding affinity (~15% of E_2; Fig. 7). The polarity of these complexes was modified to improve biodistribution without loss of binding affinity by introducing (poly)ether linkages into the 7α side chains. Attachment of a rhenium complex in position 11β (Fig. 7) was also relatively well tolerated (binding affinity ~1/10 of E_2). Tested on a reported gene, this compound displayed an agonist activity almost as strong as E_2.

Linkage of a cobalt cluster in 11β (i.e. 11β-[(ethynyl) $Co_2(CO)_6$]estradiol; Fig. 7) strongly increases the stability of the association of the parent-free ligand with the receptor. This behavior is reminiscent of the high performance of 11β-chloromethylestradiol in ER binding (almost irreversible binding in buffered solution). Tested *in vitro* in MVLN cells (MCF-7 cells stably transfected with an estrogen responsive luciferase gene), this cobalt conjugate displays a strong estrogenicity (as effective as E_2); no cytotoxicity was recorded.

4.1.3 17α Derivatives

Various organometallic moeities (rhenium, cobalt, ruthenium, tungsten, etc.) fail to strongly affect the binding affinity of E_2 for ER when linked in its 17α position at the end of a rigid ethynyl spacer (Fig. 8). In contrast, the affinity largely decreases when the spacer is shortened to a simple sp^3 carbon atom confirming that the ER-HBD possesses a subsite able to accommodate rigid narrow substituents. Affinity also decreases when the organometallic moeity is moved toward the D-ring of the steroid, even on a rigid spacer. Moreover, neutral species (ferrocenyl) are relatively well tolerated while cationic species (ruthenium) decrease the binding affinity indicating that the HBD does not accept a positive change in the 17α position of E_2. Hence, bulky organometallic moiety may be tolerated if they localize outside a zone of steric/electronic constraint.

Coordination of selected transition-metal moeities to 17α-alkynylestradiol may induce an irreversible (covalent) binding with the receptor (Fig. 8). Nucleophilic sulfur residues within or in the close vicinity of the HBD are good candidates for the establishment of such a covalent bond. The key step in this chemical reaction is the loss of the 17β-OH functionality for the generation of a carbenium ion; this electron-deficient center stabilized by the organometallic fragment

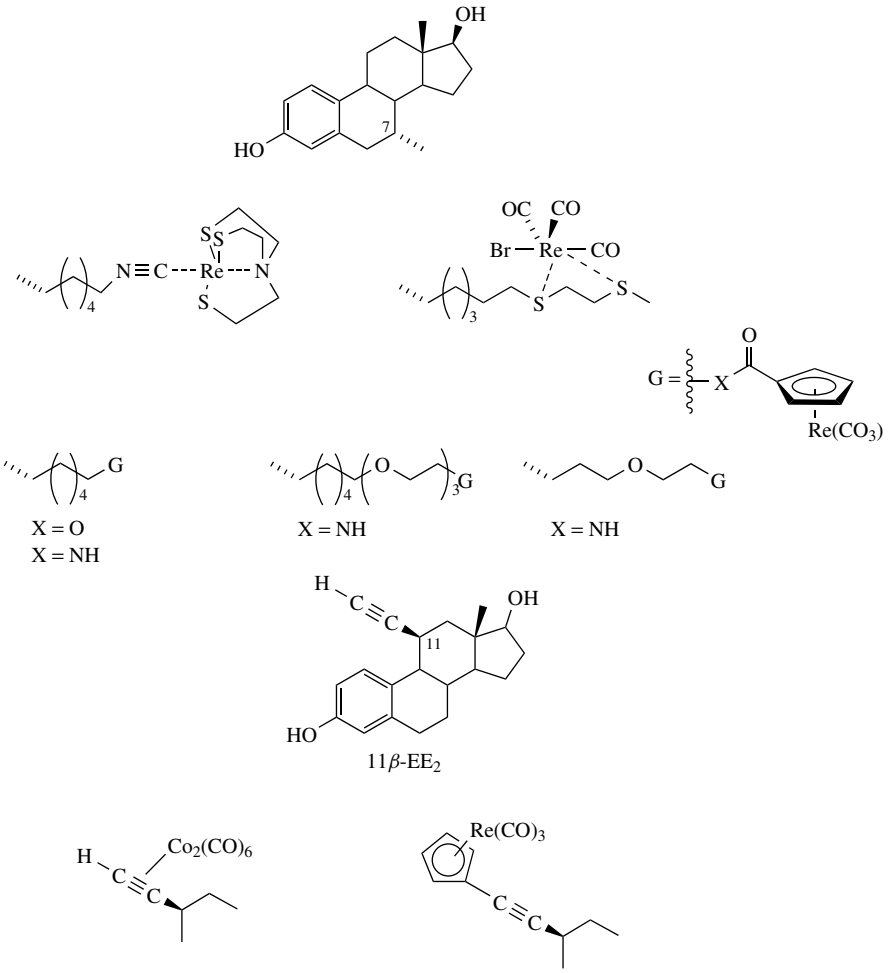

Fig. 7 Organometallic E_2 derivatives – chemical formulas of 7α and 11β derivatives described in Sect. 4.1.2.

promotes an interaction with a vicinal nucleophilic residue. Among E_2 transition-metal complexes examined, dicobalt clusters $[Co_2(CO)_6]$ were found to be the most active affinity markers. Of note, $FeCo\text{-}(CO)_6$(17α-ethynyl-17β-dehydroxyestradiol) in which the heterobimetallic fragment is sterically similar to the $Co_2(CO)_6$ homolog, prevents the formation of a carbenium-ion-like species confirming the requirement at the 17-position of an OH group and an organometallic unit capable of dissipating the positive charge of the transient carbocation.

Potential influence of covalent binding of these dicobalt clusters on the ER level and transcriptional activity is unknown, and therefore, to be investigated. Potential therapeutic activity should also be assessed. Note in this regard that alkyne $Co_2(CO)_6$ itself shows no cytotoxic effect.

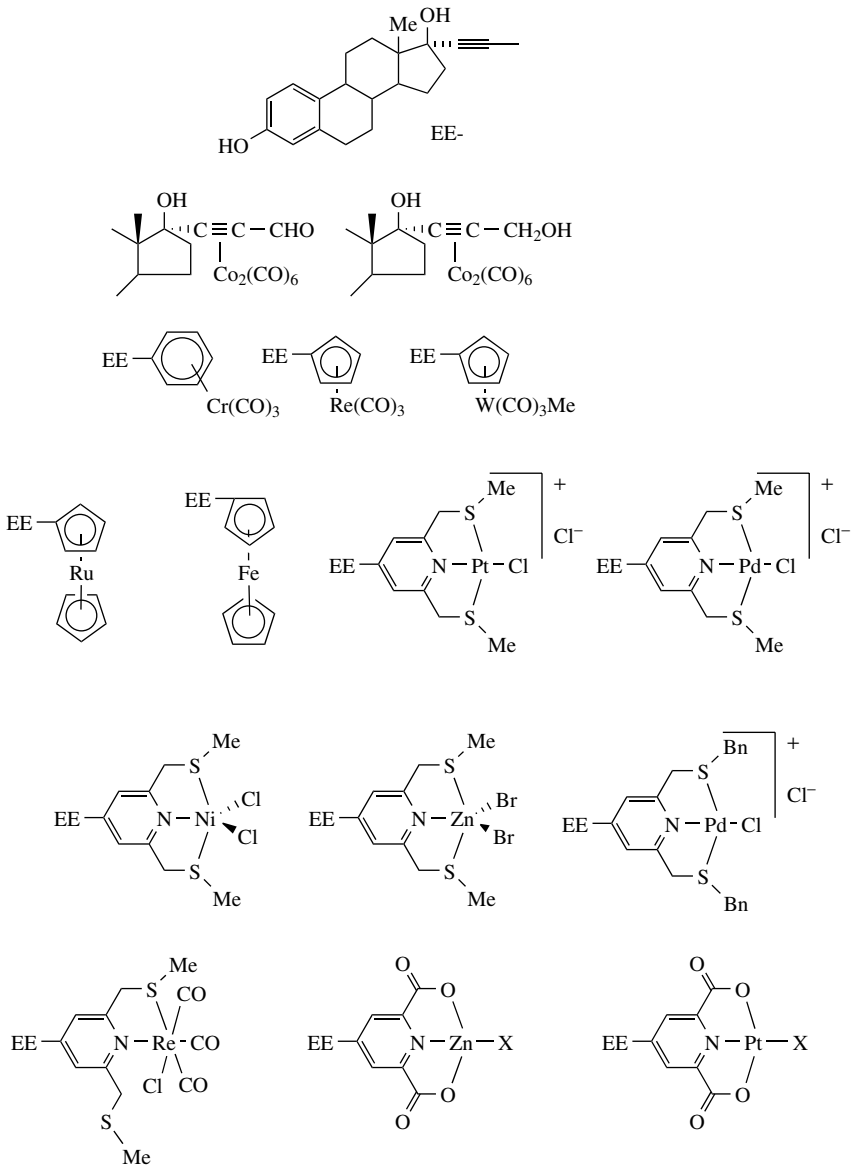

Fig. 8 Organometallic E_2 derivatives – chemical formulas of 17α ethynyl E_2 (EE) derivatives described in Sect. 4.1.3.

4.2 Radiolabeled Estradiol Derivatives

The presence of ER-positive and -negative cells in all tumors led to the concept of using receptor-directed radiochemicals of which the range of radiation is larger than one cell diameter. Compounds of this type would be of great interest since their action would not restrict solely to

ER-positive cells (as for antiestrogens) but also to ER-negative cells located in their neighborhood.

4.2.1 ^{123}I and ^{125}I Labeled Compounds

Several [^{125}I] labeled E_2 derivatives have been synthesized for *in vivo* imaging of ER-positive tumors. Utility of this approach in cancer diagnostic has, however, never been demonstrated. Nevertheless, biodistribution as well as imaging investigations performed on both animals and humans suggest some uptake selectivity, especially for 17α-iodovinyl derivatives. Stereochemistry of such compounds appears of prime importance for ER binding; *Z*-isomers bind more effectively than corresponding *E*-isomers. These data confirm the concept that the HBD possesses a hydrophobic subsite able to accept lipophilic moieties linked in position 17α of E_2 (see Sect. 3.1.4). In an effort to utilize this concept, a series of 17α-substituted E_2 derivatives were synthesized, four of them bearing iodine-123 (Fig. 9). The binding of these four compounds depends on the nature of their substituents with an alkene linkage being greatly preferred over alkynyl and alkyl. Preference for the *Z*-alkene geometry confirms the conclusion from studies on parent iodovinyls. Additional biodistribution studies performed with the *Z*-alkene suggested some uptake selectivity (uterus/ovary) and metabolic instability (accumulation of free iodine within the thyroid).

16α-[^{125}I]iodo-estradiol has been shown to produce a receptor-mediated cytotoxicity on MCF-7 breast cancer cells. The decrease of survival rate provoked

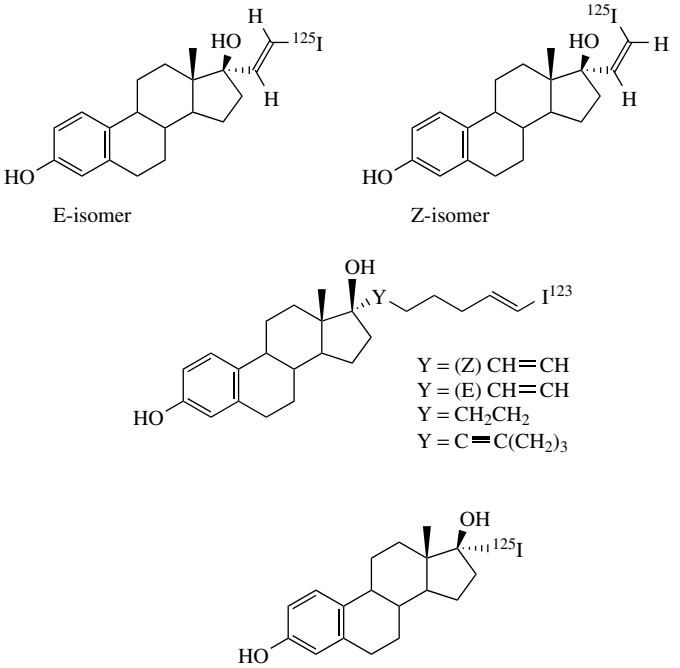

Fig. 9 Radiolabeled E_2 derivatives. Chemical formulas of iodinated (^{123}I and ^{125}I) derivatives described in Sect. 4.2.1.

by this radioligand was associated with chromosomal aberrations; of note, an excess of diethylstilbestrol, used as potential competitor, prevented the decrease of survival rate as well as chromosomal aberrations. Despite the promising aspect of these data, estimated residence times of ^{125}I-labeled estrogens in ER-positive cells (ER half-life: less than 3 h) appear be too low for an efficient cell killing. In this regard, the Auger electron-emitting nucleotides such as iodine-123 that release their energy within a short period of time would be more powerful to selectively kill ER-positive cells (i.e. half-life of ^{123}I = 4.4 h vs ^{125}I = 60 days). Testing of 17α-[^{123}I]iodovinyl-11β methoxy-estradiol on Chinese hamster ovary cells expressing or not high level of ER provided credence to this concept.

4.2.2 α-Emitting Compounds

Auger electron emitter agents would only affect ER-positive cells due to their weak distance of irradiation potency. α-particle emitting radionucleotides such as astatine-211 are attractive candidates to palliate this gap and affect neighboring ER-negative cells (range of radiation in tissue is 10 to 100 µm); astatine-211 can substitute iodine in many syntheses making the production of ^{211}At-labeled E_2 easily feasible. In fact, [^{211}At]astatinovinylestradiol (as well as its 11β methoxylated derivative) has been established. One may hope that such compounds produce a cytotoxic effect as their ^{125}I-labeled analogs.

The possibility to generate α-emitting isotopes by boron capture therapy is another approach under exploration. Boron-10, when irradiated with low energy thermal neutrons, yields α-particles and ^{7}Li-nuclei. The success of this therapy is dependant on the quantity of boron-10 and thermal neutrons to deliver to the cancer cells to sustain an α-lethal radiation. Carboranes (dicarba-closo-dodecaboranes) are a class of carbon-containing polyhedral-boron clusters having remarkable thermal stability and exceptional hydrophobic character; they have been utilized to incorporate a large number of boron atoms into tumor cells. Remarkably, hydrophobic interactions between carboranes and ER may occur when linked to a phenol. This finding led to the design of several compounds sharing high binding affinity for the receptor as well as estrogenic and/or antiestrogenic activity on an ER-dependent reporter gene (i.e. analogs of E_2, OH-Tam or RU 39,411; Fig. 10). One may speculate that such drugs may play a role in cancer therapy since they combine suitable endocrine and radiotoxic properties.

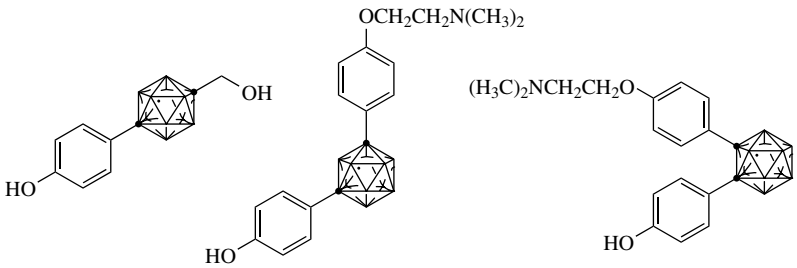

Fig. 10 Chemical formulas of phenolic carboranes with structural and ER binding properties to (a) E_2, (b) OH-Tam, and (c) RU 39,411 (Sect. 4.2.2).

4.3
Electrophilic 11β Derivative

Estrogenic and antiestrogenic activity of a few 11β-ethyl, butyl, and decyl derivatives of E_2 bearing various electrophilic functionalities (i.e. bromide, bromoacetamido, (methylsulfonyl)oxy, and (*p*-tolylsulfonyl)oxy) were determined with MVLN cells (ER-dependent luciferase expression). Ethyl derivatives were mainly estrogenic, whereas butyl and decyl essentially antiestrogenic (most compounds share a significant binding affinity for ER).

Long-term treatment of MVLN cells with OH-Tam progressively abolishes the ability of cells to express luciferase in response to estrogens. This irreversible effect seems to result from an epigenetic mechanism, such as methylation or chromatin remodeling rather than gene mutation. It progressively affects the whole-cell population and occurs by a first-order process, with

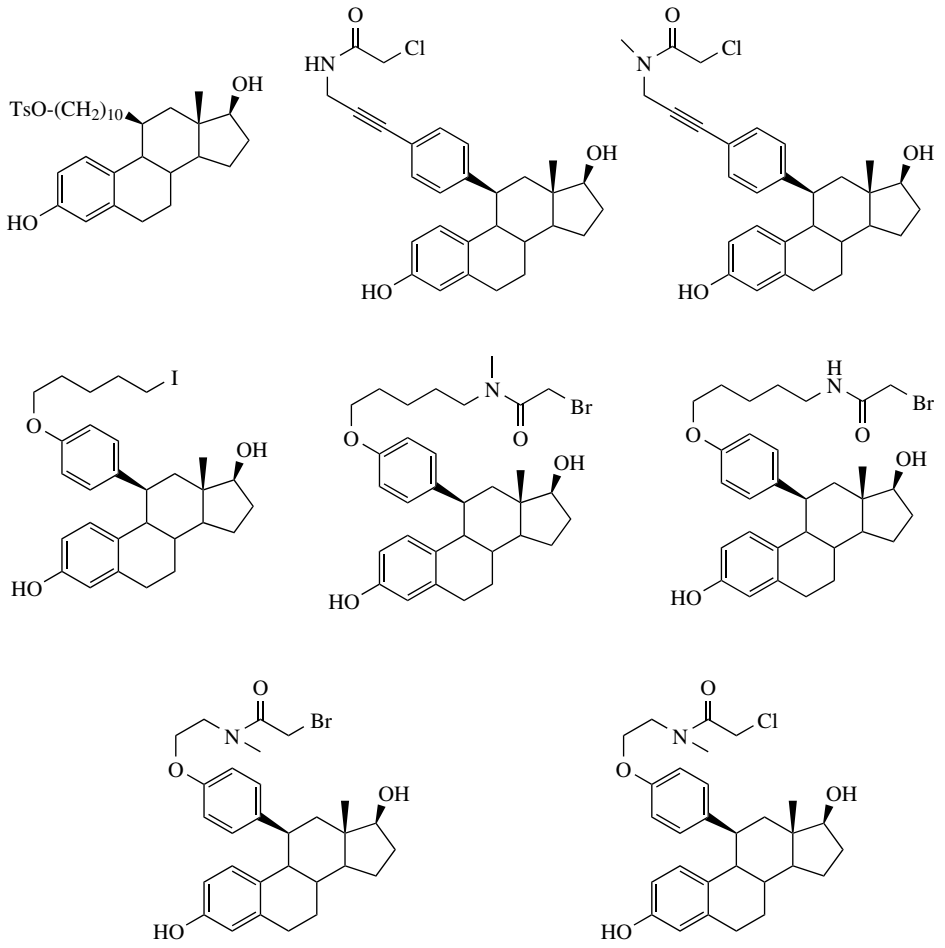

Fig. 11 Electrophilic derivatives of E_2 described in Sect. 4.3.

a half-inactivation time of ~10 days. 11β electrophile conjugates described here, similarly suppresses the expression of the luciferase gene; antiestrogenic electrophiles were more potent than the estrogenic ones but less efficient than OH-Tam. Of note, these antiestrogenic electrophiles decrease cell proliferation with potency less than OH-Tam.

These effects could not be ascribed to an irreversible binding of the compounds to ER since 11β-[(tosyloxy)decyl]E_2 (Fig. 11) solely shared such a property. A cysteine residue does not seem to be involved in the covalent attachment of this compound since it was not prevented by a thiol-specific alkylating reagent (MMTS). In fact, length and mobility of the *N*-decyl side chain precluded the identification of the anchorage site. To overcome this drawback, 11β aryl analogs aimed to restrict the localization of the electrophilic carbon to the β-side of the steroid were synthesized (Fig. 11). Both cysteinyl (probably C381 and/or C530) and non-cysteinyl residues located on the β-side and remote from C11 of the steroid (distance > "seven bonds") appear to be potential electrophile covalent attachment sites for such E_2 derivatives.

As for most other estrogens bearing reactive groups, no data were reported upon their potential use in antitumor therapy.

Keywords

Antibody
A protein product of B cells that combines with a specific molecular target called an antigen.

Antigen
A substance that interacts with an antibody.

Epitope
The region of an antigen that is directly recognized by a specific antibody.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Edited by Robert A. Meyers.

ISBN: 3-527-30543-2

Immunogen
A substance that elicits an antibody response.

Indirect Immunofluorescence (IIF)
A technique whereby an antibody is overlaid onto an antigen containing cellular substrate and the antigen–antibody formed complex is detected by a fluorescently labeled anti-antibody.

Autoimmunity is an immunological reaction against constituents of the organism that are normally tolerated by the immune system of that organism. Autoimmune reactions can be either cell- or antibody-mediated. Autoantibodies are therefore antibodies that recognize normally tolerated cell and tissue constituents (or autoantigens). The antigenic specificity of an autoantibody can be a useful aid in clinical diagnosis. Autoantibodies are either cell (or tissue) specific, as found in organ-specific autoimmune diseases such as autoimmune thyroiditis, or non–organ-specific and reactive with ubiquitous intracellular antigens, as found in multisystem autoimmune diseases such as the systemic rheumatic diseases. The latter group includes autoantibodies that recognize components of macromolecular complexes of nucleic acids and/or proteins such as small nuclear ribonucleoprotein (snRNP) particles, nucleosomal and subnucleosomal structures, and tRNA synthetases, which are intrinsic components of all cell types present in an organism. Autoantibodies also recognize components of subcellular structures, including mitochondria, ribosomes, Golgi apparatus, nuclear membrane, and substructures within the nucleus and nucleolus. The ability of autoantibodies to recognize components of the cellular machinery of replication, transcription, RNA processing, RNA translation, and protein processing has made them important reagents for isolating cDNA clones that code for proteins involved in these cellular processes and for probing the relationship between molecular and cellular structure and function. The evolutionarily conserved nature of many autoantigens allows the use of autoantibodies to identify their target antigens in diverse species, ranging in some cases from humans to lower eukaryotes such as yeast. Autoantibodies have been used to inhibit the biological function of autoantigens and/or to recognize autoantigens in a defined functional state.

1
Autoantibodies and Autoimmunity

An autoimmune response is an attack by the immune system on the host itself. In healthy individuals, the immune system is ''tolerant'' of its host (''self'') but attacks foreign (''nonself'') constituents such as bacteria and viruses. The ability to distinguish self from nonself is considered to be the determining factor in whether the immune system responds to a suspected challenge. Although it may appear obvious, there is actually considerable debate over

what constitutes ''self'' and ''nonself,'' and what cellular/molecular mechanisms are involved. Possible discriminators between ''self'' and ''nonself'' include recognition of infection or identification of danger signals. The outcome of the debate on self/nonself discrimination notwithstanding, autoimmunity represents an obvious disruption of the mechanism by which the immune system regulates its activities. Importantly, the responsible effector mechanisms appear to be no different from those used to combat exogenous infective reagents, and include soluble products such as antibodies (humoral immunity) as well as direct cell-to-cell contact resulting in specific cell lysis (cell-mediated immunity). No single mechanism has been described that can account for the diversity of autoimmune responses or the production of autoantibodies. Figure 1 outlines the common features of hypothetical models of autoantibody elicitation. Most models, particularly those relating to autoimmune disease in animals, include a genetic predisposition. Breeding experiments between inbred strains of mice have shown that the genetic control of autoantibody production is complex, involving multiple genes. Although most of the required genetic elements remain to be characterized, it appears that both acceleration and suppression of autoimmune responses are under genetic control. The most frequently observed genetic requirement involves the major histocompatibility complex (MHC) class II genes, which encode proteins responsible for the presentation of processed antigen to $CD4^+$ T cells via the T-cell receptor.

The most perplexing and challenging aspect of autoimmunity and autoantibody elicitation is the identification of the events involved in the initiation of the response. Although these early events are poorly understood for most autoimmune diseases, it is thought that an exogenous trigger can provide the first step in the initiation of some autoimmune responses. The best evidence for this comes from drug- and

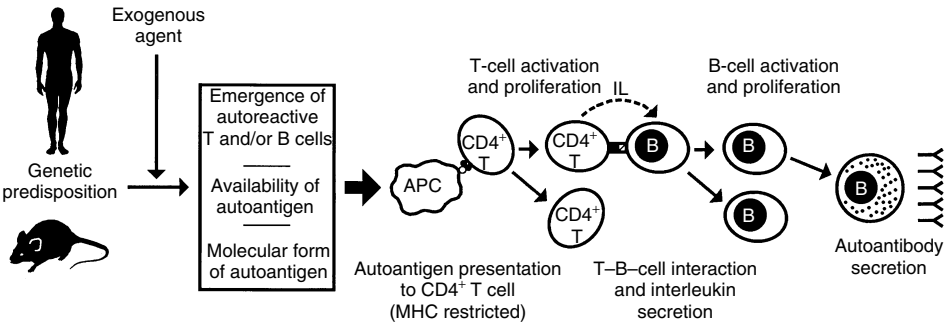

Fig. 1 Hypothetical pathway of autoantibody elicitation in human disease and experimental animal models. This model combines features from the most commonly accepted postulated mechanisms for autoantibody production. Genetically predisposed individuals may be triggered to begin the response by an exogenous agent such as exposure to a drug, chemical toxin, or other environmental influence. The events that follow (listed in large box) are poorly understood but must involve the emergence of autoreactive lymphoid cells and the presence of autoantigen in a molecular form reactive with autoreactive cells. Once the presentation of autoantigen has activated autoreactive lymphoid cells, the production of autoantibody proceeds essentially as it would for a nonautoimmune antibody response.

chemical-induced autoimmunity, which has been described in both human disease and animal models of autoimmunity. However, even in exogenously induced autoimmunity, many of the events between the administration of a chemical or a drug and the appearance of autoantibodies remain to be unveiled. Induction of autoantibodies by exogenous agents can take from several weeks to many months. Drug-induced systemic autoimmunity in humans can take prolonged periods of time to develop and can be provoked by a large number of chemically unrelated drugs. The autoantibody response, however, appears quite restricted, targeting histones and histone–DNA complexes, the components of chromatin. Complexes of drug and autoantigen are not the immunogens responsible for the autoantibody response, since the drug is not required for autoantibody interaction with the autoantigen. Withdrawal of the drug often leads to cessation of clinical symptoms, clearly implicating the participation of the drug in some mechanism inciting the autoimmune response, although the autoantibody may persist for months in the absence of the drug. In several animal models, exposure to chemicals, particularly inorganic forms of heavy metals such as mercury, silver, or gold, can lead to autoantibody expression within weeks. In these murine models, the autoantibody response is again restricted, but here the predominant targets are nonchromatin components of the nucleolus. The development of restricted autoantibody specificities in humans given many different drugs or in mice given heavy metals suggests that it is not the parent molecule that is important but rather the metabolic products of these compounds that lead on the one hand to antichromatin autoantibodies and on the other to antinucleolar antibodies. In human drug-induced autoimmunity, a common pathway of oxidative metabolism via the ubiquitous neutrophil has been suggested as a means of producing reactive drug metabolites that may perturb immune regulation sufficiently to produce autoimmune disease. Another mechanism that has been proposed is disruption by drug metabolites of positive selection of T cells during their development in the thymus. This mechanism has been shown to result in mature $CD4^+$ T cells that are able to respond to self-antigen leading to T-cell proliferation as well as autoantibody production by B cells.

In Fig. 1, the large boxed area highlights several concepts that form pivotal points in many hypothetical postulates of autoantibody elicitation but about which little is known. How do B- and T cells, with receptors for autoantigen, emerge from and escape the regulatory mechanisms that normally keep them in check, then make their way to the secondary lymphoid tissues? Studies involving transgenic mice possessing neoautoantigens suggest that possible mechanisms include avoidance of apoptotic elimination, escape from tolerance induction, and reversal of an anergic state. Molecular identification of autoantigens, their presence in macromolecular complexes, the occurrence of autoantibodies in different components of the same complex, and the appearance of somatic mutations in the variable regions of autoantibodies have suggested that it is the autoantigen that drives the autoimmune response. It remains unclear how autoantigens, particularly intracellular autoantigens, are made available to autoreactive lymphoid cells, and what molecular forms of these complex macromolecular structures interact with autoreactive lymphoid cells. One mechanism that has been proposed as a means by which autoantigens

might be made available to the immune system is apoptotic cell death. The impetus for this hypothesis is the finding that many autoantigens undergo proteolytic cleavage during apoptotic cell death and that apoptotic bodies (debris from dying cells) contain multiple autoantigens. Processing and presentation of such material by antigen-presenting cells (APC) has been suggested as a means of providing antigen to autoreactive T cells. However, uptake of apoptotic cellular material does not lead to the activation of APCs, which is necessary if APCs are to activate T cells. Inability of apoptotic material to activate APCs may stem from the observation that apoptosis is a descriptor for programmed cell death (PCD), which is a physiological process. This contrasts sharply with necrotic cell death, which is a nonphysiological process that produces cellular material that activates APCs. Also of note is that necrotic cell death induced by mercury leads to proteolytic cleavage of the autoantigen fibrillarin. Immunization with the N-terminal fragment of such cleavage leads to autoantibodies against fibrillarin that possess some of the characteristics of the antifibrillarin response elicited by mercury alone. In contrast, the antibody response elicited by immunization with full-length fibrillarin does not mimic the mercury-induced response, suggesting that processing and presentation of fragmented autoantigens may allow loss of self/nonself discrimination. Examination of the molecular forms of autoantigens during and after cell death and their roles in activating both APC and T cells will be fruitful areas of future research.

Roles in autoantibody production have been argued for pathways that either are or are not dependent on the presence of T cells. A T cell–dependent response is shown in Fig. 1 with an APC supplying processed antigen to $CD4^+$ T cells. An essential element in any model of autoantibody elicitation is the emergence of antibody-secreting B cells, which recognize material derived from the host. The antibody secreted by a B cell is directed against a single region (or epitope) on an antigen. An autoantibody response can target a number of epitopes on any one antigen, clearly showing that multiple autoreactive B-cell clones are activated during an autoimmune response. In the systemic autoimmune diseases, many autoantigens are complexes of nucleic acid and/or protein, and an autoimmune response may target several of the components of a complex. It is unknown whether the autoantibody responses to the components of a complex arise simultaneously, sequentially, independently, or through interrelated mechanisms.

In only a few diseases have autoantibodies been shown to be the causative agents of pathogenesis (e.g. antiacetylcholine receptor autoantibodies in myasthenia gravis, antithyroid stimulating hormone receptor autoantibodies in Graves' disease). It is noteworthy not only that these diseases are organ specific but also that their autoantigens are extracellular or on the surface of cell membranes and are therefore easily targeted by the immune system. In some individuals, the largest organ, the skin, can suffer insult from several blistering conditions now known to be autoimmune diseases characterized by autoantibodies against products of keratinocytes. The autoantigens involved are cell adhesion molecules that are important in maintaining the integrity of the skin by cell–cell contact between the various cell layers in the epidermis and at the dermal–epidermal junction. In

the non–organ-specific autoimmune disease systemic lupus erythematosus (SLE), anti–double-stranded DNA (dsDNA) autoantibodies have been shown to participate in pathogenic events by way of complexing with their cognate antigen to cause immune complex–mediated inflammation. These examples show that in both the organ-specific and systemic autoimmune diseases, *in vivo* disposition of autoantibody in tissues and organs has clinical significance inasmuch as it indicates sites of inflammation, which may contribute to the pathological process. Moreover, detection of autoantibody deposits in the organ-specific autoimmune diseases has particular significance because some organ-specific autoantibodies have been found to be the direct mediators of pathological lesions. In most autoimmune diseases, however, it has not been determined whether autoantibodies cause or contribute to disease or are merely a secondary consequence of the underlying clinical condition.

2 Autoantibodies as Diagnostic Markers

The diseases associated with autoantibodies can be divided into two broad groups: the organ-specific autoimmune diseases, in which autoantibodies have the ability to react with autoantigens from a particular organ or tissue, and the multisystem autoimmune diseases, in which autoantibodies react with common cellular components that appear to bear little relevance to the underlying clinical picture. In both cases, particular autoantibody specificities can serve as diagnostic markers (Table 1).

In the multisystem autoimmune diseases, there are several features of the relationship between autoantibody specificity and diagnostic significance that bear consideration. Autoantigens in these diseases are components of macromolecular structures such as the nucleosome of chromatin and the small nuclear ribonucleoprotein (snRNP) particles of the spliceosome, among others. Autoantibodies to different components of the same macromolecular complex can be diagnostic for different clinical disorders. Thus, the core proteins B, B′, D, and E, which are components of the U1, U2, and U4–U6 snRNPs and are antigenic targets in the anti-Smith antigen (Sm) response in SLE, are different from the U1 snRNP–specific proteins of 70 kDa, A and C, which are targets of the anti-nRNP response in mixed connective tissue disease (MCTD; see Table 1). It has also been observed that certain autoantibody responses are consistently associated with one another. The anti-Sm response, which is diagnostic of SLE, is commonly associated with the anti-nRNP response, but the anti-nRNP response can occur without the anti-Sm response, in which case it can be diagnostic of MCTD. These two observations suggest that the snRNP complexes responsible for the autoantibody response against the spliceosome in MCTD may differ from the snRNP complexes that produce the antispliceosome response in SLE. Other autoantibody responses demonstrate similar associations and restrictions. The anti-SS-A/Ro response (see Table 1) frequently occurs alone in SLE, but the anti-SS-B/La response in Sjögren's syndrome is almost always associated with the anti-SS-A/Ro response. Similarly, the antichromatin response occurs alone in drug-induced lupus but is usually associated with the anti-dsDNA response in idiopathic SLE.

Tab. 1 Examples of clinical diagnostic specificity of autoantibodies.

Autoantibody specificity[a]	***Molecular specificity***	***Clinical association***
Organ-specific autoimmune diseases		
Antiacetylcholine receptor*	Acetylcholine receptor	Myasthenia gravis
Anti-TSH receptor*	TSH receptor	Graves' disease
Antithyroglobulin*	Thyroglobulin	Chronic thyroiditis
Antithyroid peroxidase*	Thyroid peroxidase	Chronic thyroiditis
Antimitochondria*	Pyruvate dehydrogenase complex	Primary biliary cirrhosis
Antikeratinoctye*	Desmoplakin I homologue	Bullous pemphigoid
Antikeratinoctye*	Desmoglien	Pemphigus foliaceus
Multisystem autoimmune diseases		
Anti–double-stranded DNA*	B-form of DNA	SLE
Anti-Sm*	B, B′, D, and E proteins of U1, U2, U4–U6 snRNP	SLE
Anti-nRNP	70 kDa, A and C proteins of U1-snRNP	MCTD, SLE
Anti-SS-A/Ro	60 and 52 kDa proteins associated with hY1-Y5 RNP complex	SS, neonatal lupus, SLE
Anti-SS-B/La	47 kDa phosphoprotein complexed with RNA polymerase III transcripts	SS, neonatal lupus, SLE
Anti-Jo-1*	Histidyl tRNA synthetase	Polymyositis
Antifibrillarin*	34 kDa protein of box C/D containing snoRNP (U3, U8, etc.)	Scleroderma
Anti-RNA polymerase 1*	Subunits of RNA polymerase 1 complex	Scleroderma
Anti-DNA topoisomerase 1 (anti-Scl-70)*	100 kDa DNA topoisomerase I	Scleroderma
Anti-centromere*	Centromeric proteins CENP-A, B, C	CREST (limited Scleroderma)
Canca	Serine proteinase (proteinase 3)	Wegener's vasculitis

[a] Disease-specific diagnostic marker antibodies indicated by an asterisk.
Notes: SLE: systemic lupus erythematosus; MCTD: mixed connective tissue disease; SS: Sjögren's syndrome; cANCA: cytoplasmic antineutrophil cytoplasmic antibody; TSH: thyroid-stimulating hormone; CREST: calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, telangiectasia.

Autoantibody specificities may occur at different frequencies in a variety of diseases, and the resultant profile consisting of distinct groups of autoantibodies in different diseases can have diagnostic use. In some cases, the grouping of autoantibody specificities, such as the preponderance of antinucleolar autoantibodies in scleroderma (Table 1), provides provocative but as yet little-understood relationships with clinical diagnosis. Unlike SLE, where a single patient may have multiple autoantibody specificities to a number of unrelated nuclear autoantigens (e.g. DNA, Sm, SS-A/Ro), scleroderma patients infrequently

have multiple autoantibody specificities to nucleolar autoantigens that are unrelated at the macromolecular level (i.e. not part of the same macromolecular complex).

3 Autoantibodies as Molecular and Cellular Probes

Autoantibodies can be used for the detection of their cognate antigens using immunoprecipitation, immunoblotting, enzyme-linked immunosorbent assay (ELISA), and a variety of microscopy techniques including immunoelectron microscopy. The most visually impressive demonstration of the usefulness of autoantibodies as biological probes is the indirect immunofluorescence (IIF) test. In this technique (Fig. 2), a cell or tissue source containing the autoantigen of interest is permeabilized, to allow entry of the antibody into the cell, and fixed, to ensure that the target antigen is not leached away during the procedure. Although some procedures are inappropriate for particular antigens, workable means of cell permeabilization and fixation have been developed. The cell substrate is incubated with the autoantibody to allow interaction with the antigen, and any excess is washed away. The location of the antigen/autoantibody complex within the cell is revealed by addition of an anti-antibody tagged with a fluorochrome. Fluorescence microscopy is then used to view the cells to determine the location of the antigen-/autoantibody-/fluorochrome-tagged anti-antibody complex. Using this technique, investigators are identifying an increasing number of autoantibody specificities that recognize cellular substructures and domains (Table 2, Figs. 3 and 4). The nucleus can be identified by a variety of autoantibodies such as those against chromatin and DNA or, as shown in Fig. 3(a), autoantibodies to the nuclear lamina, which underlies the nuclear envelope and produces a ringlike fluorescence around the nucleus. The nucleolus and its subdomains can also be identified by a variety of autoantibody specificities (Table 2). Autoantibodies against the 34 kDa protein fibrillarin, a component of the C/D box containing small nucleolar ribonucleoprotein (snoRNP) particles, label the nucleolus in a distinctive ''clumpy'' pattern (Fig. 3e). The list of autoantibodies that are able to distinguish subnuclear domains and compartments, some considerably smaller than the nucleolus, continues to grow. One example is the Cajal body, a small subnuclear structure described using light microscopy by the Spanish cytologist Santiago Ramon y Cajal in 1903 and subsequently named after him. This nuclear domain can now be easily identified using human autoimmune sera that react with p80 coilin (Fig. 3d), a protein highly enriched in the Cajal body. Using other autoantibodies, it has been found that Cajal bodies contain snRNP particles and fibrillarin (previously thought to be restricted to the nucleolus and prenucleolar bodies). Knowledge of the functional associations of these coiled-body constituents suggests that the Cajal body may play a role in RNA processing and/or in the accumulation of components involved in RNA processing.

Many features of subcellular structures such as size, shape, and distribution can be studied by IIF during the cell cycle, viral infection, mitogenesis, or any cellular response that may result in changes in the distribution of an antigen or a subcellular structure. As shown in Fig. 3(a) (arrowheads), antinuclear lamin autoantibodies can be used to reveal re-formation of the lamina during telophase. Autoantibodies

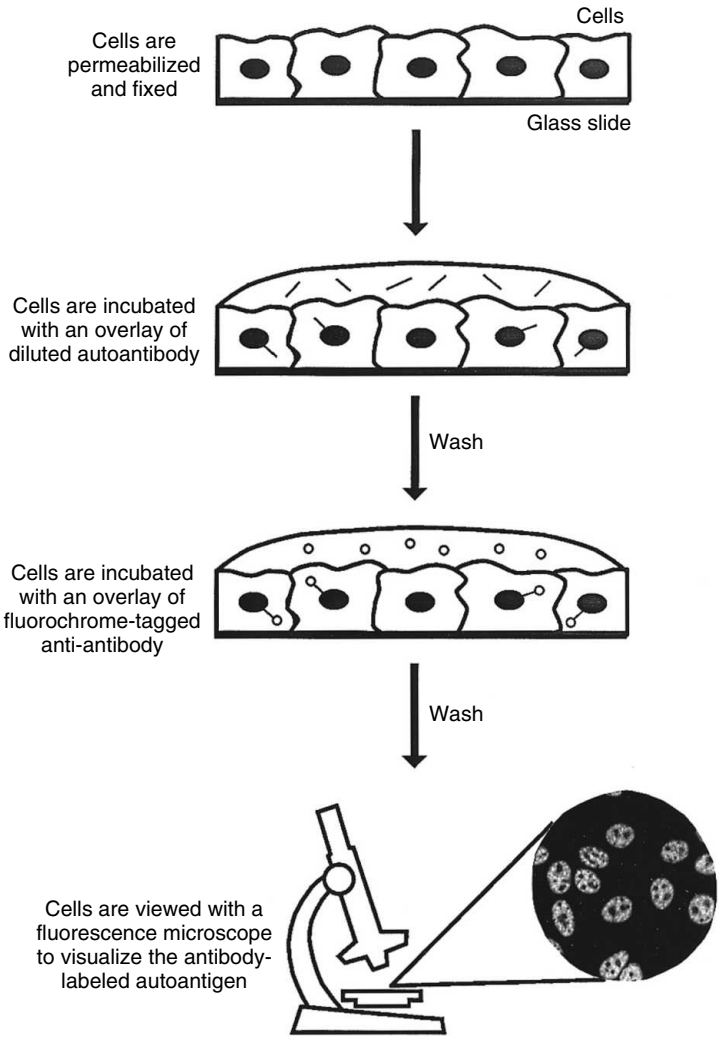

Fig. 2 Diagrammatic representation of the steps involved in the indirect immunofluorescence (IIF) test: see text for explanation.

have identified unexpected protein distributions such as the localization of the nucleolar protein fibrillarin to the outer surface of the chromosomes during cell division (Fig. 3e, arrowheads). The localization of some autoantigens during the cell cycle has aided in their identification. Detection of proliferating cell nuclear antigen (PCNA) in S-phase cells (Fig. 3c) suggested its involvement in DNA synthesis, while the distribution of speckles along the metaphase plate produced by other autoantibodies (Fig. 3f, arrowheads) was an important clue in their identification as autoantibodies to centromeric proteins A, B, and C.

The IIF test has also proved useful in the identification of autoantibodies

Tab. 2 Examples of subcellular structures and domains recognized by autoantibodies.

Autoantibody	*Molecular specificity*	*Subcellular structure*
Nuclear components		
Antichromatin	Nucleosomal and subnucleosomal complexes of histones and DNA	Chromatin
Anti-nuclear pore	210 kDA glycoprotein (gp210)	Nuclear pore
Antilamin	Nuclear lamins A, B, C	Nuclear lamina
Anticentromere	Centromere proteins (CENP) A, B, C, F	Centromere
Anti-p80 coilin	p80-coilin (80 kDa protein)	Coiled body
Anti-PIKA	p23–25 kDa proteins	Polymorphic interphase karyosomal association (PIKA)
Anti-NuMA	238 kDa protein	Mitotic spindle apparatus
Nucleolar components		
Antifibrillarin	34 kDa fibrillarin	Dense fibrillar component of nucleolus
Anti-RNA polymerase 1	RNA polymerase 1	Fibrillar center of nucleolus
Anti-Pm-Scl	75 and 100 kDa proteins of Pm-Scl complex	Granular component of nucleolus
Anti-NOR 90	90 kDa doublet of (human) upstream binding factor (hUBF)	Nucleolar organizer region (NOR)
Cytosolic components		
Antimitochondria	Pyruvate dehydrogenase complex	Mitochondria
Antiribosome	Ribosomal P-proteins (P_0, P_1, P_2)	Ribosomes
Anti-Golgi	95 and 160 kDa golgins	Golgi apparatus
Antiendosome	180 kDa protein	Early endosomes
Antimicrosomal	Cytochrome P450 superfamily	Microsomes
cANCA	Serine proteinase (proteinase 3)	Lysosomes
Antimidbody	38 kDa protein	Midbody
Anticentrosome/centriole	Pericentrin (48 kDa)	Centrosome/centriole

Notes: NuMA: nuclear mitotic apparatus; Pm-Scl: polymyositis-scleroderma; cANCA: cytoplasmic antineutrophil cytoplasmic antibody.

that react with subcellular structures other than the nucleus. Figure 4 shows the IIF patterns produced by some of these autoantibodies. Prior knowledge of subcellular organelles and their relative cellular distribution was instrumental in identifying the structures recognized by these and other autoantibodies. In turn, autoantibodies, by virtue of their reactivity with individual autoantigens, have allowed cell and molecular biologists an insight into the molecular constituents of these subcellular organelles.

Comparative studies using human autoantibodies, and nonhuman autoantibodies raised by immunization against specific cellular proteins, can be useful in determining the cellular distribution of the specific protein. This is achieved by using antihuman antibodies labeled with one chromophore and antibodies specific for the nonhuman antibody that

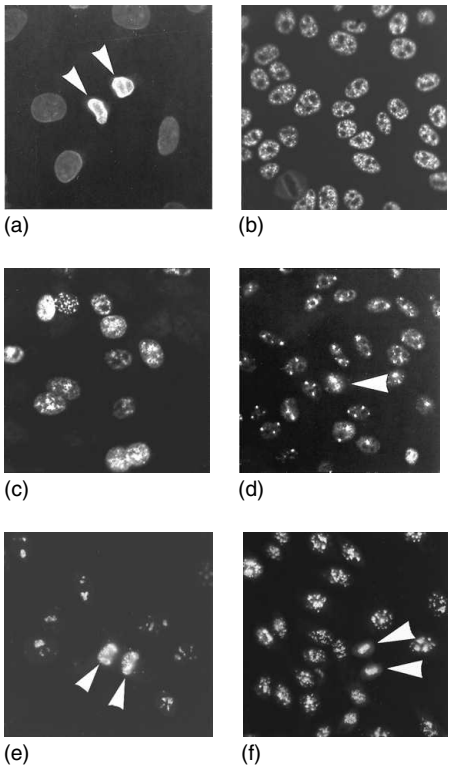

Fig. 3 Immunofluorescence patterns produced by autoantibodies recognizing structural and functional domains within the cell nucleus (magnification, 350×). (a) Antinuclear lamin B1 antibodies identify the periphery of the nucleus; arrowheads show the re-formation of the nuclear envelope during late telophase. (b) Anti-Sm antibodies localize the U1, U2, and U4–U6 snRNP particles as a speckled nuclear pattern. (c) Anti-PCNA antibodies recognize the auxiliary protein of DNA polymerase delta during active DNA synthesis, producing different fluorescence patterns as cells progress through mitosis. (d) Anti-p80 coilin antibodies highlight subnuclear domains known as Cajal bodies, which disappear during metaphase (arrowhead). (e) Antifibrillarin antibodies target the nucleolus and produce a characteristic clumpy pattern in interphase cells, decorating the chromosomes from late metaphase until cell division (arrowhead). (f) Antibodies to centromeric proteins A, B, and C produce a discrete speckling of the interphase nucleus and identify the centromeric region of the dividing chromosomes during cell division (arrowheads).

are labeled with a different chromophore and by comparing the fluorescence patterns. Immunolocalization of the non-snRNP spliceosome component SC-35 was achieved in this way by comparison of anti-SC-35 antisera with the IIF pattern of autoimmune anti-Sm sera, which recognize protein components of the spliceosome.

One feature of autoantibodies that distinguishes them from antibodies raised by specific immunization, and underscores their uniqueness, is their ability to recognize their target antigen not only from the host but also from a variety of species. The extent of this species cross-reactivity is dependent on the evolutionary conservation of the autoantigen and is related to the conservation of protein sequence. One example is the snoRNP protein fibrillarin. Using autoantibodies in a variety of immunological techniques, including IIF, this protein can be recognized from species as diverse as humans and the unicellular yeast *Saccharomyces cerevisiae*. cDNA cloning of fibrillarin has confirmed the expected high degree of conservation of the protein sequence.

The reactivity of autoantibodies with conserved sequence and conformational protein elements has made them useful reagents in the cloning of cDNAs of expressed proteins from cDNA libraries from a variety of species. However, because of their reactivity with the human

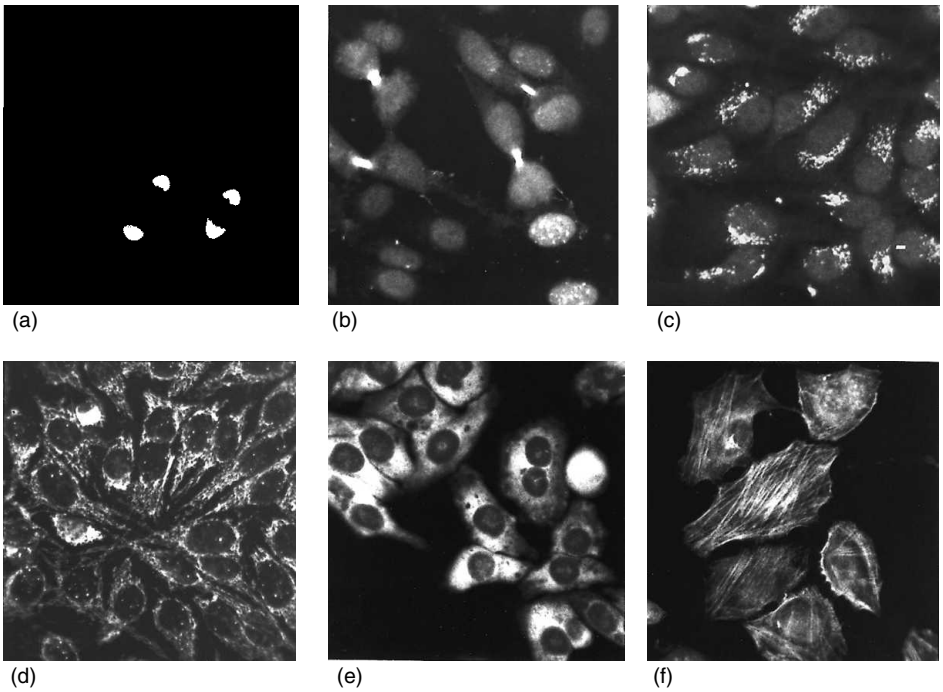

Fig. 4 Immunofluorescence patterns produced by autoantibodies recognizing intracellular structures other than the nucleus. (a) Antimitotic spindle apparatus antibodies identify spindle poles and spindle fibers during cell division. (b) Antimidbody antibodies react with the bridgelike midbody that connects daughter cells following chromosome segregation but before cell separation. (c) Anti-Golgi complex antibodies decorate the Golgi apparatus, which in most cells is shown as an accumulation of fluorescence in a discrete cytoplasmic region. (d) Antimitochondrial antibodies demonstrate the presence of mitochondria throughout the cytoplasm; the discrete nuclear dots represent an additional autoantibody specificity in this serum unrelated to mitochondria. (e) Antiribosome antibodies produce a diffuse cytoplasmic staining pattern that spares the nucleus but may show some weak nucleolar fluorescence. (f) Anticytoskeletal antibodies react with a variety of cytoskeletal components; in this case, the antibody reacts with nonmuscle myosin. (magnification: a, 700×; b–f, 350×).

protein they have found most use in the cloning and characterization of the primary structure of numerous human cellular proteins. This diversity of targets that can be exploited by this approach is clearly illustrated in Tables 1 and 2.

Elucidation of the structure of the autoantigens that are the targets of autoantibodies from systemic autoimmune diseases has revealed that many are functional macromolecular complexes involved in nucleic acid and protein synthesis and processing (Table 3). A distinguishing feature of many of these complexes of nucleic acids and/or proteins is that autoantibodies do not recognize all the components of the complex. An extreme, but useful, example is the ribosome, which in eukaryotes may contain more than 70 proteins. However, only the P-proteins (P_0, P_1, and P_2), S10, and L12 are recognized by autoantibodies. Nonetheless,

Tab. 3 Examples of the function of nuclear autoantigens and the effects of autoantibody on antigen function.

Autoantigen	***Function***	***Autoantibody effect***[a]
	Known function	
Sm/nRNP (U1, 2, 4–6 snRNP)	Pre-mRNA splicing	Inhibition of pre-mRNA splicing
PCNA (DNA polymerase delta auxiliary protein)	DNA replication	Inhibition of DNA replication and repair
RNA polymerase I	Transcription of rRNA	Inhibition of rRNA transcription
tRNA polymerase	Aminoacylation of tRNA	Inhibition of charging of tRNA
Ribosomal RNP	mRNA translation	Inhibition of protein synthesis
Centromere/kinetochore	Microtubule-based chromosome movement during mitosis	Inhibition of centromere formation and function
	Probable function	
Fibrillarin (Box C/D snoRNP)	Processing and methylation of pre-rRNA	Blocks translocation of fibrillarin during the cell cycle, thereby influencing the ultrastructure of the nucleolus.
NOR-90	Nucleolar transcription factor	Not tested

[a] Inhibition of function has been demonstrated *in vitro* or following injection of autoantibody into living cells.

the use of autoantibodies that identify specific components of such complexes has aided in identifying other subunits of these complexes, with profound consequences. Thus, the initial identification of anti-Sm and anti-nRNP autoantibodies in SLE led to the observation that they recognize some of the protein components of the snRNP particles, fueling subsequent studies that showed the snRNPs as components of the spliceosome complex that functions in pre-mRNA splicing.

As the functional associations of autoantigens have become known, attempts to uncover the role of the autoantigen itself have revealed that autoantibodies can directly inhibit the function of their target autoantigen (Table 3). Although it remains to be determined, it seems likely that such inhibition reflects the involvement of a conserved protein sequence or structure in functional activity. An increasing number of autoantibodies, many of unknown molecular specificity, recognize their autoantigen only in a particular functional state or phase of the cell cycle. Of the several examples known, the best characterized is PCNA, which is the auxiliary protein of DNA polymerase delta and is recognized by autoantibodies only during mitosis, even though PCNA is present throughout the cell cycle. When a population of cells at different stages of the cell cycle is used as substrate in the IIF test, anti-PCNA autoantibodies produce varying degrees of fluorescence intensity, being negative for G_0 cells and highly positive for S-phase cells (Fig. 3c). These

intriguing features of some autoantibodies have added new dimensions to the biological usefulness of these proteins and have suggested that functionally active macromolecular complexes may play a role in the elicitation of the autoantibody response.

The presence of multiple autoantibody specificities in the blood of individual human patients with autoimmune diseases poses a limitation on their use in studies involving a single autoantigen. Only infrequently are patients found whose autoantibody response is so restricted that they express autoreactivity to a single autoantigen or autoantigenic complex; such autoantibodies are termed *monospecific*. For some autoantibody specificities, this condition has been overcome by the production of hybridomas secreting a monoclonal autoantibody. Some hybridomas have been produced by fusion of B cells from human patients, but most have come from fusion of lymphoid cells from animal models of autoimmunity, particularly inbred murine strains. Monoclonal antibody specificities include reactivity against the nucleic acids DNA and RNA, subunits of chromatin, protein components of snRNP particles, fibrillarin, and immunoglobulin.

4 Autoantibodies in Experimental Models of Autoimmunity

Research into the mechanisms of autoimmunity and the antigenic specificity, and possible pathogenic role, of autoantibodies has been significantly advanced by the availability of animal models. Four different types of models have been used (Table 4). Specific antigen immunization models are produced by direct injection of purified antigen into animals to elicit autoantibody. Direct immunization has proven most useful when the autoantigen is extracellular or is on the cell membrane. In such examples, the elicited autoantibody response can produce pathological consequences such as the myasthenia gravis–like disease produced in rodents following immunization with purified acetylcholine receptor. The animals used in this type of model are most often healthy, normal individuals with fully functional immune systems and are able to downregulate the autoimmune response produced by the immunization of autoantigen. As a result, direct immunization models often produce transient autoimmune responses and the animals return to a healthy state.

Comparison of the autoantigenic reactivities of antibodies raised by immunization, especially to intracellular autoantigens, has revealed distinct differences in comparison to autoantibodies found in human autoimmune disease. Direct immunization requires a purified antigen, which means subjecting the antigen to rigorous biophysical, biochemical, and sometimes immunological separation techniques. The resulting preparation may therefore be partially or totally denatured and no longer in association with other cellular components that constitute its *in vivo* molecular form. Even if the native *in vivo* macromolecular complex can be purified, direct immunization experiments are ''best guess'' attempts to mimic the natural autoimmunization process because the molecular structure of the putative autoimmunogen that contains the autoantigen of interest is unknown. A further complication is the use of adjuvants to boost the immune response. As a result, direct immunization produces antibodies that, although they react with the autoantigen, usually recognize a denatured form rather than

Tab. 4 Examples of animal models of autoantibody production.

Model	***Animal***	***Human disease***	***Autoantibody specificity***
Spontaneous			
NZB	Mouse	Hemolytic anemia	Erythrocyte
(NZB × NZW) F1	Mouse	SLE	Chromatin, DNA
MRL-*lpr*/*lpr*	Mouse	SLE	Chromatin, DNA, Sm, ribosome
MRL-+/+	Mouse	SLE	Chromatin, DNA, Sm
BXSB	Mouse	SLE	Chromatin, DNA
Obese strain (white leghorn chicken)	Bird	Thyroiditis	Thyroglobulin
Induced by exogenous agents			
Chronic GVHD	Mouse	SLE	DNA, chromatin, snRNP, ribosome
Mercuric chloride	Mouse (H-2^s)	Scleroderma[a] (immune-complex nephritis)	Fibrillarin (Box C/D snoRNP)
Mercuric chloride	Mouse (non-H-2 restricted)	SLE	Chromatin
Mercuric chloride	Rat ($RT1^n$)	Immune-complex nephritis	GBM
Pristane	Mouse	SLE	DNA, Sm, RNP, Su
Direct immunization (antigen)			
EAT (thyroglobulin)	Rabbit, mouse (H-$2^{k,s,\text{ or } q}$)	Thyroiditis	Thyroglobulin
GMB nephritis (GBM)	Sheep, mouse	Immune-complex nephritis	GBM
EMG (acetylcholine receptor)	Lewis rat	Myasthenia gravis	Acetylcholine receptor
Gene mutation			
C1q knockout	Mouse (MRL-+/+)	SLE	DNA, rheumatoid factor
Dnase1 knockout	Mouse	SLE	Chromatin, DNA
SAP knockout	Mouse	SLE	Chromatin, DNA
c-mer knockout	Mouse	SLE	Chromatin
IFN-γ transgenic	Mouse	SLE	DNA, histones

[a]Autoantibody specificity is specific for scleroderma, but a scleroderma-like disease has not been described in mice treated with mercuric chloride.
Notes: GVHD: graft-versus-host disease; GMB: glomerular basement membrane; EAT: experimental autoimmune thyroiditis; EMG: experimental myasthenia gravis; C1q: component of serum complement; Dnase1: deoxyribonuclease 1; SAP: serum amyloid P component; c-mer: tyrosine kinase.

the autoantigen in its native state; only rarely do they react with the autoantigen when it is in association with other cellular subunits that make up its *in vivo* molecular form. Although direct-immunization antibodies can recognize conformational epitopes, they do not appear to recognize conserved epitopes and therefore cannot exhibit the same lack of species specificity that allows, for example, antifibrillarin autoantibodies to recognize fibrillarin in all species that contain this protein. Lack of reaction against conserved epitopes means that direct immunization antibodies are less efficient at inhibiting the functional activity of their target autoantigen than autoantibodies from patients with autoimmune diseases. Animal models of other types, described next, can produce autoantibodies with reactivities that are extremely difficult to differentiate from those of human patients. As a result, such models more closely approximate their human counterparts.

The second type of model also involves the manipulation of normal, nonautoimmune animals to produce an autoimmune response. In these cases, the triggering event is the introduction of exogenous material into the animal, which, unlike the case of direct immunization, may appear to bear little relationship to the ensuing autoimmune response. An excellent example of this type of model is the autoimmunity induced by heavy metals. Administration of mercury by several different routes and in several different forms, most notably subcutaneous injection of mercuric chloride, produces in mice an autoantibody response that targets the nucleolus. The principal autoantigen involved is the 34 kDa protein fibrillarin (Fig. 5), a protein component of the box C/D snoRNP particles. Mercury induces this autoantibody response in a restricted number of histocompatibility genotypes, most commonly H-2^s. Although offspring of crosses between the autoimmune-sensitive H-2^s strains and the autoimmune-resistant strains such as C57BL/6 (H-2^b) or DBA/2 (H-2^d) are sensitive to antifibrillarin induction following $HgCl_2$ treatment, the response does not appear to be solely due to the product of a dominant *H-2* gene but involves multiple loci as well. This is supported by back-crossing of hybrids onto the autoimmune-sensitive H-2^s background, where the $HgCl_2$-induced antifibrillarin response is even less frequent, even though 50% of the mice would be expected to be homozygous for H-2^s. Although antifibrillarin autoantibodies are a marker for human scleroderma, mercury does not appear to produce a scleroderma-like disease in mice; the importance of the model lies instead in the similarity of this toxin-induced murine autoantibody's response to the spontaneous antifibrillarin autoantibody in human scleroderma.

Another example of the exogenous factor-type model is murine graft-versus-host disease (GVHD). In this model, the offspring of the mating of two inbred nonautoimmune mouse strains are injected (grafted) with lymphocytes from one of the parental strains. The injected lymphocytes recognize genetic differences in the host strain that are inherited from the other parental strain and are stimulated to mount a variety of immune responses against the host animal; hence the name "graft versus host." Unlike the case of direct immunization models, the autoimmunity produced in this type of model can lead to severe pathological consequences including lethal immune-complex disease. The immunological sequelae that occur during a GVHD response depend on the murine inbred strains used. Injection of

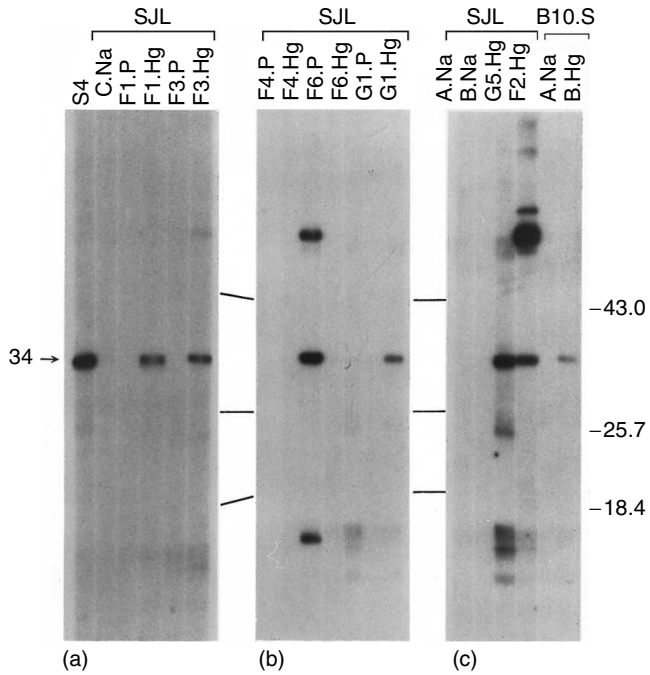

Fig. 5 Antifibrillarin autoantibodies in H-2^s murine strains (SJL and B10.S) after treatment with mercuric chloride. Autoantibodies were detected by immunoblotting using mouse liver nucleoli resolved by sodium dodecyl sulfate/polyacrylamide gel electrophoresis (SDS-PAGE). (a) Prototype human antifibrillarin serum (S4), serum from a NaCl-treated SJL mouse (C.Na), and serum from mice F1 and F3 before (P) and after (Hg) mercuric chloride treatment. (b) Immunoblotting using sera from three additional SJL mice before and after mercuric chloride treatment. (c) Immunoblotting using sera from two SJL mice treated with NaCl (A.Na; B.Na); two SJL mice treated with mercuric chloride (G5.Hg; F2,Hg); and two B10.S mice, one treated with NaCl (A.Na) and the other treated with mercuric chloride (B.Hg). (Reproduced from Hultman et al., *Clin. Exp. Immunol.* 78 (1989), 470–477 with permission from the publishers.)

DBA/2 lymphocytes into a cross between the DBA/2 and C57B16 mice produces a chronic GVHD, which results in an autoimmune response similar to human SLE including the presence of autoantibodies against chromatin and DNA. Injection of lymphocytes from the A/J strain into Balb/c X A/J hybrids also produces a chronic GVHD in which autoantibodies to snRNP particles including the U3 snoRNP are found. The relationship of different autoantibody specificities to the use of different strains of inbred mice in the GVHD model again highlights the influence of genotype on autoimmunity and autoantibodies.

The third type of model does not require any manipulation of the animal at all; the disease develops spontaneously. The best described of these are the murine strains

BXSB, (NZB × NZW) F1, NZM, MRL-+/+, and MRL-*lpr*/*lpr*, which develop forms of SLE that serve as excellent models of the autoantibody specificities and pathology of the human disease. While the variety of autoantibodies developed by these different strains continues to be investigated, the common autoantibody response, like human SLE, is against chromatin and its subcomponents including DNA. In the (NZB × NZW) F1 strain, autoimmune disease and autoantibodies occur earlier and more frequently in female mice, a finding that has been found to be associated with the presence of female sex hormones. Because of this and other features, the (NZB × NZW) F1 strain is considered the best animal model of human SLE. As noted above, it is the genetic makeup of these inbred strains that has significant potential to address the genesis of the autoimmune response. A much studied aspect of several of the spontaneous models of systemic autoimmune disease is the presence of single-gene defects that accelerate or exacerbate autoimmunity in these already susceptible mouse strains. In the MRL substrains, the *lpr* phenotype is responsible for massive lymphoproliferation of $CD4^-$, $CD8^-$, and $B200^+$ T cells and an accelerated occurrence of autoimmune phenomena compared to the MRL-+/+. Recent studies have indicated that the *lpr* defect is due to a mutation in the *fas* gene that leads to defective expression of *fas* on T- and B cells, which allows them to escape apoptotic elimination and reach the peripheral circulation. Breeding experiments to impart the *lpr* gene to nonautoimmune genetic backgrounds have shown that the *fas* defect does influence the development of autoimmunity and the expression of autoantibodies. A dominant role for *fas* in the initiation of autoimmunity and autoantibodies is questionable, however, because the MRL-+/+, which does not have the *fas* defect, does develop a autoantibody profile and immunopathological disease that is similar to the MRL-*lpr*/*lpr*, albeit at a much later age. Other genes that appear to play a role in acceleration of autoimmunity include *gld*, the ligand for *fas*, and *Yaa*, a sex-linked gene that produces a defect in B cells and is the accelerator gene of autoimmunity in the male BXSB mouse. Exposure of lupus-prone strains to exogenous agents known to elicit autoimmunity in normal mice can result in accelerated appearance of disease features including autoantibodies. In some cases, the exogenous agent accelerates the appearance of idiopathic disease, while in others the elicited disease has features of xenobiotic-induced disease. Thus, mercury exposure accelerates idiopathic disease in BXSB mice including antichromatin autoantibodies of the IgG2a subclass, while pristane injection into (NZB × NZW) F1 mice elicits anti-Sm/RNP and Su autoantibodies that are not part of the idiopathic disease of the (NZB × NZW) F1 but are found in pristane-induced autoimmunity. These observations suggest that not only idiopathic and induced autoimmunity may arise through different mechanisms but also exogenous triggers can influence disease expression.

The fourth type of model involves genetic manipulation in which a gene is deleted (''knockout'') or added (''transgenic'') in order to influence the expression of autoimmunity. Both types of genetic modification can be used to study the influence of single genes on the animal models described above. Perhaps not unexpectedly, many gene deletions have little

or no effect on the expression of autoimmunity and autoantibodies. Such negative effects need to be interpreted carefully as they may indicate a genetically redundant process rather than an unimportant gene. Other gene deletions have been reported to influence differing aspects of autoimmunity in a gene-specific manner, although the extent of the effect may vary between experimental models. Some gene deletions exhibit highly consistent responses. Thus, deletion of the gene for the pleiotropic cytokine interferon-γ (IFN-γ) abrogates autoantibody production and immunopathology in mercury-induced autoimmunity of B10.S mice and spontaneous autoimmunity in MRL-*lpr*/*lpr* mice. The significance of IFN-γ in systemic autoimmunity has been demonstrated in nonautoimmune-prone mice made transgenic for IFN-γ expression in the epidermis. The increased expression of IFN-γ leads to a lupus-like disease characterized by the production of autoantibodies and immune complex–mediated tissue damage. Further evidence for the importance of IFN-γ has come from an examination of gene expression in the Nba2 locus of chromosome 1 of the mouse. Nba2 is a genetic interval identified as a locus of genetic susceptibility for lupus in the NZB strain. The offspring of Nba2 interval–specific congenic C57BL/6 mice mated with NZW mice develop autoimmunity similar to the SLE-prone (NZB × NZW) F1 mouse. Examination of gene expression by DNA array revealed a relationship between increased expression of interferon inducible gene (*Ifi*) 202 and features of systemic autoimmunity. Importantly, the gene for Ifi202 lies within the Nba2 interval. Confirmation that increased expression of Ifi202 occurs in other models of systemic lupus would significantly enhance its stature as a lupus susceptibility gene. However, as susceptibility for SLE maps to multiple genetic loci, it is highly likely that additional genes contribute to full disease expression in the (NZB × NZW) F1 mouse.

A number of other gene deletions are associated with expression of autoimmunity and autoantibodies. Some of these such as deficiency of C1q, a component of the complement system, have particular relevance as complement deficiencies in humans and can lead to development of systemic lupus. Significantly, lack of C1q is not sufficient for the development of murine lupus; this gene deletion must occur on genetic backgrounds carrying additional susceptibility genes for autoimmunity to occur. It must also be noted that although many knockout and transgenic models exhibit features of autoimmunity, they may also exhibit other features that are not consistent with the known spectrum of clinical and immunological facets of autoimmune diseases. More telling is the finding that many of the genetic mutations that lead to autoimmunity in mice are not necessary for the development of human systemic autoimmune disease. As described above, mutation in the *fas* gene contributes significantly to the severity of murine SLE. However, mutations in the *fas* gene are not associated with human SLE but rather with autoimmune lymphoproliferative syndrome (ALPS). ALPS is characterized by lymphoproliferation of double-negative T cells and autoantibodies against DNA and cardiolipin, features found in mice with a *fas* mutation but without other lupus susceptibility genes. Similarly, Dnase1-deficient mice develop a lupus-like disease with antichromatin autoantibodies, but deficiency of Dnase1 is not common in human systemic lupus. A nonsense mutation in exon 2 of the *DNASE1* gene has been reported in two apparently unrelated young Japanese

patients but not in SLE patients in Spain or the United States.

Although care must be taken in their interpretation, identification and characterization of genes that are associated with autoimmunity and autoantibody production constitute fertile ground for the molecular biologist. Elucidation of the roles of the many genes that appear to contribute to the development of autoimmunity will help define the critical molecular events in the disease process. The murine strains described above have proven valuable model systems for studies on a variety of facets of autoimmunity, and will play significant roles in future genetic studies. It will be important to focus attention not only on the genetic loci that impart susceptibility to autoimmunity but also on those that may allow an individual to resist the development of autoimmune phenomena.

5 Perspectives

Initially used as aids in clinical diagnosis, autoantibodies have become increasingly useful ''reporter'' molecules in the identification of structure–function relationships. New autoantigens continue to be discovered, while many described autoantigens remain to be characterized both structurally and functionally. Autoantibodies will figure prominently in these characterization studies. As the molecular structures of the interaction between autoantigen and autoantibody become known, it should be possible to design peptide configurations capable of perturbing the functional activity of numerous cellular processes.

Understanding the influence of genes and their products not only on susceptibility but also on resistance to autoimmunity and autoantibody expression is in its infancy. However, the tools to mature this field (inbred animal models of spontaneous and induced autoimmunity, and the molecular techniques of transgenics and gene knockout) are already available. They await the complex but potentially fruitful identification and functional analysis of candidate genes.

Anticentromere Antibodies
A centromere is the essential domain for proper segregation of chromosomes to daughter cells at mitosis and meiosis. Antibodies to the centromere are found in about 20% of patients with scleroderma, almost all of whom have limited scleroderma, formerly called *CREST* (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia) syndrome.

Antitopoisomerase I Antibodies
Anti-DNA topoisomerase I antibodies, formerly termed *anti-Scl-70* antibodies, recognize a nuclear enzyme that catalyzes the relaxation of supercoiled DNA. The presence of antitopoisomerase I antibodies is highly specific to scleroderma sera. Antitopoisomerase I antibodies identify a scleroderma subset with a high frequency of diffuse skin thickening and pulmonary interstitial fibrosis.

Epitope
Antigenic determinants recognized by T and/or B cells are called *immunogenic epitopes*. Recombinant techniques of antigens can yield information crucial to uncovering T- and B-cell epitopes. Epitopes in autoimmunity can be expanded to other epitopes on the same protein or other proteins in the same macromolecular complexes, a phenomenon termed *epitope spreading*.

Recombinant Protein
Large amounts of antigen can be expressed by introducing its cloned gene into *Escherichia coli* or insect cells. Fusion proteins consisting of the amino-terminal peptides encoded by a portion of the *E. coli* β-galactosidase or a glutathione S-transferase peptide linked to eukaryotic proteins have been used often.

Scleroderma
Scleroderma is a multisystem disorder of unknown etiology characterized by abnormal deposition of collagen in the skin and internal organs, and microvascular obliteration. Circulating autoantibodies are one of the features of scleroderma.

Scleroderma is a multisystem connective tissue disease of unknown etiology characterized by abnormal deposition of collagen in the skin and internal organs, and microvascular obliteration. Several autoantibodies against cellular components are striking features of scleroderma and some are associated with certain clinical subsets. This article mainly reviews the autoimmune phenomenon against centromere antigens and topoisomerase-I, which are commonly found in the limited skin sclerosis type and the proximal type respectively. For the production of autoantibodies, molecular mimicry hypothesis and implications of apoptosis are also discussed.

1
Scleroderma and Autoantibodies

1.1
Methods of Autoantibody Detection

Sera from human autoimmune patients contain autoantibodies that react with many important cellular antigens. Detection of antinuclear antibody (ANA) is widely accepted as an important test in the diagnosis of many connective tissue diseases such as systemic lupus erythematosus, scleroderma, Sjögren's syndrome, and polymyositis. ANA testing by indirect immunofluorescence (IIF) is commonly used as a broad screen for the detection of a variety of autoimmune diseases. Initially, ANA tests by IIF methods were performed on mouse kidney or rat liver tissue sections, but lately many laboratories use HEp-2 human larynx epithelioma cancer cell line as substrate. Human cultured cells are better for the detection of human and proliferating nuclear antigens. In contrast to a few specific fluorescent patterns for particular antigens, the main patterns in IIF studies are not specific for any autoantibodies or disease entity. Characterization of the specific antibodies using double immunodiffusion assay, enzyme-linked immunosorbent assay (ELISA), or immunoblotting with appropriate reference sera is necessary. Immunoblotting with an extract from cultured cells is a very sensitive assay and permits detection of autoantibodies against soluble and insoluble antigens. This method has proved useful in a number of studies to characterize many autoantigens. Since expression cloning was first applied to isolation of autoantigens in 1985, cloned autoantigens themselves have been used for diagnostic autoantibody determination, molecular analysis of autoimmune epitopes, and molecular investigation of autoimmune processes. More recently, many clinical laboratories use commercial ELISA kits with cloned recombinant autoantigens, which are often expressed by *E. coli*. Although there might be the lack of proper folding or protein modification of some recombinant proteins obtained from prokaryotic sources, ELISA is highly sensitive, quantitative, and suitable for simultaneous analysis of a large number of serum samples, providing substantial cost and time savings.

1.2
Clinical Subsets of Scleroderma and Autoantibodies

Connective tissue disease patients have various autoantibodies against a variety of cellular components required for universal

cell functions such as cell division, DNA replication, transcription, and translation. Although the primary event that triggers production of autoantibodies is not known, more than 95% of scleroderma patients produce autoantibodies to nuclear components. Scleroderma (systemic sclerosis) is a disease characterized by collagen deposition and subsequent fibrosis in skin and internal organs. The extent of fibrosis shows considerable variation in severity, which classifies scleroderma into two distinct subtypes: the limited cutaneous form and diffuse form. In the former, skin thickening is relatively restricted to the fingers, hands, and/or face but without extension to other internal organs. In the latter, skin changes are widespread and often rapidly progressive, involving the trunk and distal and proximal portions of the extremities with internal organ involvement. In addition, some patients have overlapping features with other connective tissue diseases.

ANAs in patients with scleroderma can be mainly classified into antinuclear and antinucleolar antibodies by immunofluorescence staining patterns of tissue culture cells as substrate (Fig. 1). The former is further subdivided into several distinct nuclear staining patterns: discrete speckles (almost equal to the centromere), coarse speckles, diffusely grainy, and homogeneous. The latter is divided into speckled, homogeneous, and clumpy. With these distinctive autoantibodies, a number of targeted autoantigen molecules have been identified: DNA topoisomerase I (topo I, formerly described as Scl-70), three centromere proteins (CENP-A, CENP-B, and CENP-C), PM/Scl (polymyositis/scleroderma)-associated antigens, RNA polymerases, and fibrillarin (U3 RNP-associated 34 kDa peptide).

Among autoantibodies against these antigens, two antibodies have been well correlated with subtypes of scleroderma:

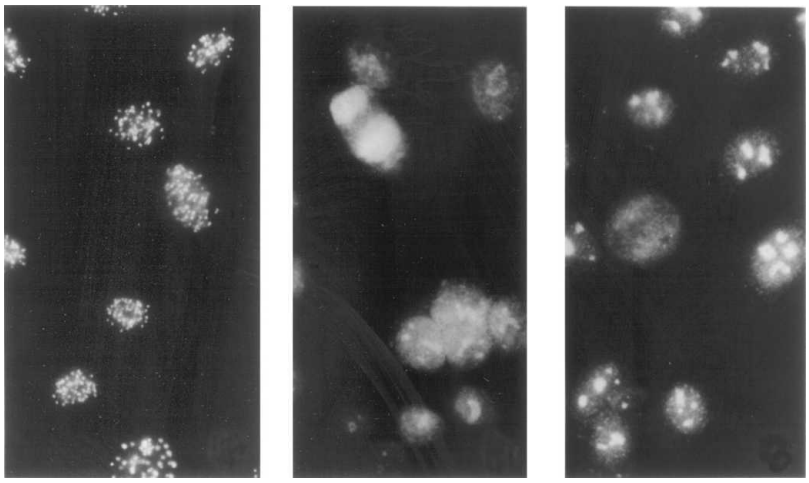

Fig. 1 Indirect immunofluorescence pictures of HEp-2 cells with scleroderma sera. (a) Anticentromere antibody. (b) Antitopoisomerase I antibody. (c) Antifibrillarin antibody.

anti-topo I and anticentromere antibodies (ACA). The former antibody has been frequently found in the patients with diffuse scleroderma, while the latter has been strongly associated with limited scleroderma. Furthermore, Fritzler et al. reported that no anti-topo I was found in more than 127 patients with connective tissue diseases other than scleroderma, while ACA was found in only less than 2% of 113 patients with connective tissue diseases other than scleroderma and Raynaud's disease. In addition, the coexistence of these two antibodies in the same patient is very rare. Therefore, both antibodies show striking disease associations and are found almost exclusively in patients with scleroderma.

Nevertheless, ACA and anti-topo I–positive patients constitute only a half or two-thirds of scleroderma patients (Table 1). The remaining one-third or another half are patients without ACA or anti-topo I. Although the latter percentage may decrease when the detection system of these autoantibodies is improved, other autoantibodies are also present in patients with distinct subsets of scleroderma, and sometimes even coexist with ACA or anti-topo I antibody. For example, some individuals with diffuse scleroderma have anti-RNA polymerase (RNA polymerase I, II, III) antibody or antifibrillarin antibody, and others in overlap with polymyositis have anti-PM/Scl antibody.

The characterization of these scleroderma subset-specific autoantibodies will be helpful in the diagnosis and prognosis of the patients with scleroderma as well as in the study on the mechanism of

the immunization process in scleroderma autoimmunity.

1.3 Detection of Scleroderma Autoantibodies and Epitope Analysis

Detection of the scleroderma autoantibodies depends on the assay systems. For example, Kumar et al. reported that the anti-topo I sera that were positive on the immunoblot were only 71 to 86% positive in the immunodiffusion test. Similar results were obtained by Hildebrandt; anti-topo I IgG were 88% positive by ELISA with the purified topo I from calf thymus, in contrast to being 100% positive by immunoblotting. In addition, Maul et al. reported that a few anti-topo I–negative sera were positive by double diffusion with the recombinant protein blotted on the membrane. Sensitivity of ACA detection was also compared by Hildebrandt et al. among ELISA, immunoblotting, and IIF. IgG-ACA was detected to be 85% by ELISA with cloned C-terminal CENP-B antigen, 95% by immunoblotting with HeLa chromosomal proteins, and 100% by IIF with HEp-2 cells. These results indicate that among the above detection systems, immunoblotting seems to display a comparable sensitivity for the detection of these autoantibodies, even if these antigens have some conformational epitope (described below).

Epitope mapping studies have been performed more extensively with B-cell than with T-cell studies because autoantibodies (B cells) are easy to handle. Various approaches have been used for the studies; for example, deletion-type immunoblotting experiments with recombinant fragments of the autoantigen and ELISA with synthesized peptides covering the whole sequence of the autoantigen. The former method somehow detects conformational epitopes, consisting of amino acid residues from distant regions in the sequence of a protein that are spatially juxtaposed upon, while the latter method is suitable for the detection of linear epitopes in the primary structure of a protein. Since the epitope regions are renatured to some extent during protein transfer and while blocking the membrane, the immunoblot analysis can reveal the linear and conformationally reversible epitopes.

The major autoantigens associated with scleroderma are shown in Table 1: topo I, CENP-A, CENP-B, CENP-C, 75 kDa and 100 kDa antigens of PM/Scl, and fibrillarin. Epitope analyses of the epitope structure for these autoantigens at the molecular level would provide a significant insight into the interactions between the antigen and the autoantibodies. What are the trigger components leading to autoimmune response? (pathogens? or the antigens themselves?) Are there some characteristic features of structures targeted by autoantibodies? How are autoantibodies related to the disease process? We focus on the epitope structure of scleroderma autoantigens, mainly describing the analysis of centromere antigens.

2 Centromere Antigens

2.1 Autoimmunity against Centromere Antigens

The attachment site of spindle microtubules on mitotic chromosomes is called the *centromere*. The centromere has a

central role in the pairing and disjunction of daughter chromosomes in mitosis and meiosis. The human centromere at the metaphase chromosome has a trilaminar disk-shaped structure that was revealed on electromicroscopic observation, which is called the *kinetochore*.

Moroi et al. first reported ACA in the sera of patients with scleroderma in 1980. ACA is recognized as a "disease marker" antibody of limited cutaneous scleroderma, which was formerly called *CREST syndrome*. In addition, ACA are indispensable probes for the analysis of the structure of the centromere/kinetochore.

The IIF pattern by ACA is discrete speckled nucleoplasmic staining in interphase cells and strong centromeric dots decorated in the metaphase plate (Fig. 1a). Three major target autoantigens, *cen*tromere *p*rotein (CENP)-A, B, and C, have been identified with ACA-positive sera. Earnshaw et al. first isolated cDNA encoding CENP-B, the 80 kDa human centromere autoantigen, by expression cloning. Next, Saitoh et al. isolated cDNA clones that encode the human CENP-C, 140 kDa human centromere autoantigen, with immunoscreening. As for CENP-A, the 17 kDa histone-like centromere antigen, Sullivan et al. cloned its bovine cDNA using PCR with degenerated oligonucleotides derived from the amino acid sequences previously reported by Palmer et al. and isolated its human homologue. These three antigens exist in the centromere during cell cycles (Fig. 2). In contrast, the 330 kDa CENP-F antigen localizes in the centromere from metaphase

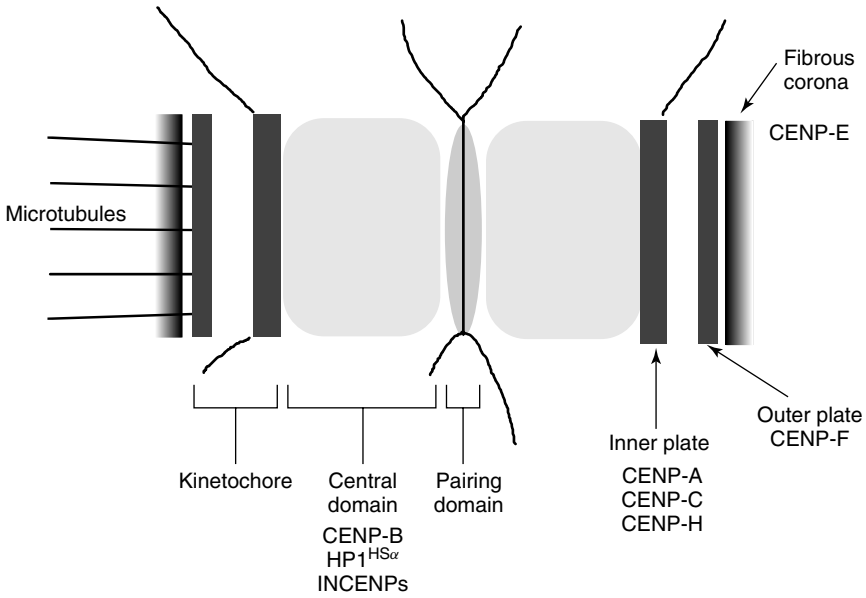

Fig. 2 Centromere domain and centromere antigens. Elements of centromeric region are depicted mainly for CENPs and autoantigens. Centromere proteins are divided into two groups: one is the constitutive proteins, for example, CENP-A, -B, -C, and -H, and another is the chromosome passenger proteins, for example, CENP-E and -F. Some proteins shown here have not been reported as autoantigens, for example, CENP-H and INCENPs.

to anaphase. Rattner et al. reported that autoantibodies to CENP-F were found mainly in patients who suffered from malignant tumors but not systemic autoimmune disease and rarely found them in ''classical'' ACA-positive sera, which detect CENP-A, B, and C. Its cDNA was also isolated by immunoscreening with human autoantibodies, while a cDNA that encoded human CENP-E was isolated using experimentally induced monoclonal antibodies by immunization of fractionated chromosomal proteins. CENP-H cDNA was incidentally obtained by differential display. cDNA clones of CENP-D and -G, which were also shown to be recognized by ACA, have not been obtained. Although several proteins that are not named ''CENP'' are known to exist in the centromere region – centromere-chromatin proteins and centromere-associated proteins – they are rarely targeted by ''classical'' ACA.

2.2 CENP-B and B-cell Epitopes

We start with CENP-B epitopes since its gene was cloned at first and has been most extensively studied. CENP-B has 599 amino acid residues and an apparent molecular mass of 80 kDa, larger than the predicted molecular weight of 65 kDa. This antigen was used for the demonstration of the direct interaction between the constitutive centromeric protein and centromeric satellite DNA (alphoid DNA). Alphoid DNA is a long, tandemly repeated DNA family based on a 171 bp fundamental monomer repeat unit. The alphoid DNA family in humans is composed of many subclasses, which share varying degrees of sequence homology (60–90%) and have been localized to the primary constriction (centromere) of specific chromosomes. Masumoto et al. found that the CENP-B antigen directly interacts with an alphoid DNA and they named the 17 bp motif required for the specific binding ''CENP-B box.'' The DNA binding domain of CENP-B is located within the N-terminal 125–amino acid region containing 4 potential α-helices. On the contrary, the C-terminus of the protein from 541 to 599 amino acids forms a homodimer by itself (Fig. 3). Thus, CENP-B was presumed to contribute to the formation of the heterochromatin structure in the centromere region, binding to alphoid

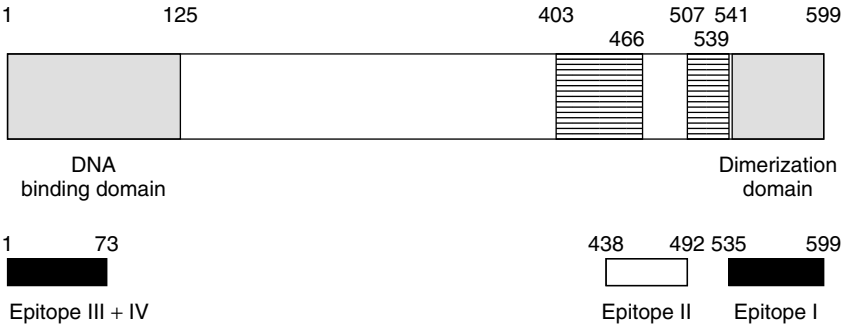

Fig. 3 Functional domains and autoepitopes of CENP-B. The top rectangle represents the full-length human CENP-B antigen. Two horizontal lined boxes show highly acidic regions. Major autoepitopes, which are recognized by more than 50% of ACA, are shown as black bars. Minor epitope, which is recognized by less than 50% of ACA, is shown as a white bar.

DNA at the N-terminus, and forming a homodimer at the C-terminus.

Epitope mapping of CENP-B were conducted to deduce the important antigenic regions for autoimmunity reactions against human centromere. Bacterial recombinant proteins expressed from a set of truncated CENP-B cDNAs were used for immunoblotting analysis. From the C-terminus to the N-terminus, four representative epitopes have been shown, epitopes I to IV. Epitopes III and IV locate in the N-terminal 73 residues corresponding to the N-terminal half of the DNA binding domain. They are overlapping since the N-terminal boundary of epitope III has not yet been precisely determined. Interestingly, the inhibitory effect of the patients' sera containing antibodies against epitopes III and/or IV on the DNA binding activity was shown *in vitro*, while no inhibitory effect was observed with ACA-positive sera without reactivities to these epitopes. Epitope III plus IV (1–73) reacts with ~75% of the ACA-positive sera. In contrast, almost all ACA sera reacted with the region spanning amino acids 535 to 599, the epitope I, which corresponds to the region required for its homodimerization. In order to restrict a minimal region of epitope I, further studies for epitope mapping were performed but no shorter reactive region in epitope I was identified. The epitope I, a major epitope of CENP-B, is used as a substrate of ELISA for ACA for clinical use.

CENP-B is a highly conserved protein through species. The similarity of the amino acid sequences of CENP-B between mouse and human are 96%. Amino acid sequences of the epitopes I, III, and IV are identical between the two species. In contrast, the epitope II (438–492), which is only reactive to the minority of ACA, is called a ''human specific'' epitope because the antibody to this region did not react to mouse centromere. Actually, this epitope has lower homology to amino acid sequences for CENP-B between human and mouse. This fact supported an idea that the autoantibodies were derived from stimulation of the autoantigen itself, consistent with the ''antigen driven theory.'' In addition, the antigenic pleural sites in a single molecule also supported this theory. For ordinary antibodies' and antigens' interaction, 15 to 24 residues of the antigen participate in antibody binding. As for the epitopes I and II, we could not limit the region below the 30 to 40 amino acid length. These results supported the idea that some conformational structures in the epitopes were required for the interaction between the antibodies and antigens.

In order to confirm the importance of protein conformation for antigenicity, we tried a DNA immunoprecipitation method for quantitative assays of ACA. A ^{32}P radio-labeled 59 bp oligonucleotide probe, including the 17 bp motif of the CENP-B box, bound with cellular purified CENP-B proteins was immunoprecipitated and the radioactivity was used for the estimation of anti-CENP-B/DNA complex–antibody activity. Even though no ACAs reacted to only DNA molecules, a few sera without reactivities to CENP-B in immunoblotting methods did immunoprecipitate the CENP-B/DNA complex. Such a discrepancy of results between the DNA immunoprecipitation method and the immunoblotting as well as that relatively long stretches of amino acids were required for epitope mapping led us to an idea that the conformational structure was critical for the epitope targeted by some autoantibodies.

2.3 CENP-C and B-cell Epitopes

CENP-C is an essential component of the inner plate of the trilaminar structure of the kinetocore. It is required for maintaining proper kinetochore size and is implicated in the metaphase-to-anaphase transition in mitotic cells by stabilizing microtubule attachments. It also has a DNA binding domain and a region that contributes to the formation of the homodimer as described above for CENP-B. CENP-C has 943 amino acids and an apparent molecular mass of 140 kDa in SDS-PAGE, quite larger than the molecular weight derived from the sequence. Autoepitopes of CENP-C were mainly restricted to three regions that correspond to functional domains (Fig. 4). Epitope 1, the first major epitope, resides at the N-terminus (74–244 a.a.) that corresponds to the presumptive instability domain reported by *in vivo* analysis. Epitope 7 located at the central part (396–552 a.a.) contains the DNA binding domain, which was recently shown to bind the alphoid DNA selectively – the CENP-C region between amino acids 410 and 537. Together with CENP-B, CENP-C associates with the centromeric alphoid DNA *in vivo* and defines a highly structured organization within the human centromere. Epitope 9, the other major epitope, locates in the C-terminal region that contributes to the formation of the homodimer. This epitope spanning a 124 amino acid stretch from 476 to 599 is the second major epitope. Autoimmunity to this region was quite unique.

By immunoblotting, the reactivities between monomer and homodimer formed by chemical cross-linking were compared. The reactivities as well as the frequencies of the antibodies against the dimer form were obviously higher in both IgG and IgM responses. Interestingly, GroEL protein, which is a heat-shock chaperon protein of *E. coli*, was copurified with the C-terminal region. When purified antibodies against the dimer in a liquid phase containing GroEL were applied to various assays to detect ACA, they did not react to the recombinants but very weakly recognized cellular CENP-C by immunoblotting. Furthermore, they did show centromere staining in IIF analysis. These results suggest that these purified antibodies recognize predominantly native forms of centromere structures. Therefore, there are assumed

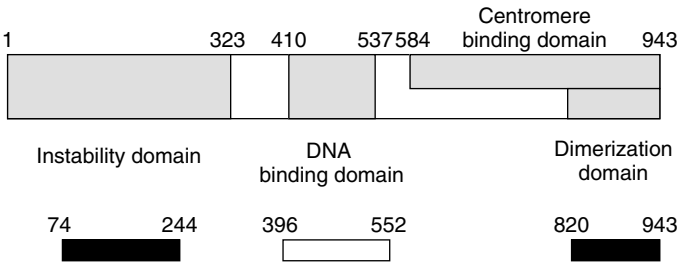

Fig. 4 Functional domains and autoepitopes of CENP-C. The top rectangle represents the full-length human CENP-C antigen. Major autoepitope, which is recognized by more than 50% of ACA, is shown as a black bar. Minor epitope, which is recognized by less than 50% of ACA, is shown as a white bar. For the epitope at the C-terminus, the dimer form is recognized by around 50% of ACA (see text).

to be three different types of epitopes on the C-terminus, each specific to a linear sequence, a three-dimensional structure newly formed by a dimer complex, and the conformational structure formed by a macromolecular complex in the presence of GroEL.

2.4 CENP-A and B-cell Epitopes

CENP-A is also a component of the inner plate of the trilaminar structure of the kinetocore. It has 140 amino acids and a molecular weight of 17 kDa (Fig. 5). Because of the presence of the region homologous to histone H3 in the C-terminal half, it is considered to function as a centromere-specific core histone. This region shares 62% identity with histone H3 and is called the *histone fold* domain. Although the N-terminal region from 1 to 48 residues is unique for CENP-A, its localization to the centromere is dependent on the histone fold domain. Nevertheless, the two-third part of the C-terminal peptide of CENP-A showed no reactivity to ACA.

The basic amino acids in the N-terminus may be involved in the protein–protein interaction with an acidic protein(s) or the DNA binding activities. Brendel et al. suggested that autoantigens generally contain more long charge runs or clusters of charged groups, which may be exposed on their surface and be strongly immunogenic, and consist of extended surface structures that are charge-, proline-, or glycine-rich. Two peptides composed of amino acid residues 3 to 17 (named peptide A) and residues 25 to 38 (peptide B) were synthesized and examined for the reactivity to ACA. Peptide A contains seven arginine (R), one lysine, and three proline (P), and two repeats of PRRRS. Peptide B has a few charged residues (two arginine and one histidine) but contains two dipeptide Pro-Ser or one Ser-Ser, leaving each of the three residues (PSXXXPSXXXSS) and two repeats of Gly-Pro-Ser. Interestingly, nearly 90% of ACA showed reactivity to both peptides. These two, epitopes 1 and 2, are the major autoepitopes. Peptide A was further used by Valdivia et al. to produce experimental ACA in rabbits and its strong antigenicity was demonstrated. Additional epitope(s) is present in the region between 39 to 52 amino acid residues, but very minor populations of ACA have reactivities.

2.5 Centromere-associated Autoantigens

Heterochromatin protein 1 (HP1) was first identified in *Drosophila* as a nonhistone chromosomal protein that functions in the establishment and maintenance of higher-order chromatin structures playing a role in chromosome segregation and gene silencing. Three related proteins homologous to *Drosophila* HP1

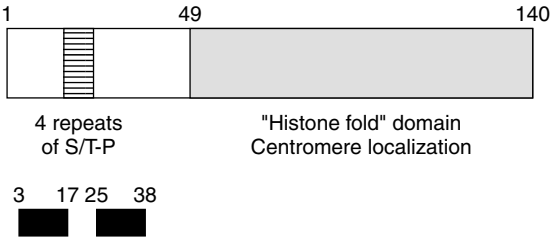

Fig. 5 Functional domains and autoepitopes of CENP-A. The top rectangle represents the full-length human CENP-A antigen. Major autoepitopes, which are recognized by more than 80% of ACA, are shown as black bars.

have been found in humans. They are closely related and contain two functionally important and conserved domains: N-terminal chromo and C-terminal chromo shadow domains. Three human homologues $HP1^{HS\alpha}$, $HP1^{HS\beta}$, and $HP1^{HS\gamma}$ are targeted by "antichromo antibodies" in a subset of ACAs. Interestingly, antichromo antibodies are always associated with ACAs. Furuta et al. reported that 20% of ACA-positive sera also had antichromo antibodies that targeted p23 ($HP1^{HS\gamma}$) and p25 (a mixture of $HP1^{HS\alpha}$ and $HP1^{HS\beta}$).

$HP1^{HS\alpha}$, which has 191 amino acids, was used for epitope mapping with immunoblotting. Regions 1 (16–43) and 2 (106–191) were found to be important for autoepitopes and in the two conserved regions: chromodomain (13–78) and chromo shadow domain (114–179). Since $HP1^{HS\alpha}$ localizes in the inner centromeric region of mitotic chromosomes and antichromo antibodies are exclusively found in ACAs, ACA is likely to recognize maculomolecular antigenic complexes. Interestingly, some ACA-positive sera were found to develop antichromo antibodies after a long period. This phenomenon implies "epitope spreading," which means that the epitope is spreading to another molecule or to domains of the same molecule.

Another autoantigen targeted by a minor subset of ACA has been characterized by ACA-positive patients. This antigen, p27, has 199 amino acids with a predicted molecular weight of 22 kDa and was nomenclatured "SSSCA1" (*S*jögren *s*yndrome/*sc*leroderma *a*utoantigen 1). Many charged residues (17 acidic and 12 basic) are present in the N-terminal region (7–83 a.a.) and two short Pro-rich stretches are present in the remaining region (113–122 and 138–145 a.a.). So far, it is not known whether p27 is a structural component such as a centromere-associated protein; however, the exclusive association between antibodies against p27 and the centromere is suggestive of a biological interaction between these antigenic molecules. Interestingly, Zhou et al. showed that p27 as well as CENP-B, fibrillarin, and RNA polymerase II was overexpressed in fibroblasts from scleroderma patients.

3 Topoisomerase I

3.1 Autoimmunity against Topoisomerase I

In the eukaryotic cell, the topological status of DNA is modulated by DNA topoisomerases. Topo I causes a single-strand break, which can allow the two sections of DNA helix on either side of the nick to rotate freely relative to each other. This enzyme plays important roles in chromatin organization, DNA replication, recombination, and transcription. It localizes in the nucleoplasm, nucleolus, and nucleolar organizing regions, giving IIF staining patterns of speckled nucleolar and densely speckled nucleoplasmic decoration (Fig. 1b). Racial differences in the prevalence and autoepitopes of anti-topo I antibodies are noted. Immunoglobulin isotypes are IgG, IgA, and IgM, and their frequencies are IgG $>=$ IgA $\gg$ IgM. Isotype switch with persistence of IgG expression in longitudinal studies and the presence of all four IgG anti-topo I subclasses suggest chronic B-cell stimulation by antigen-driven mechanism.

3.2 B-cell Epitope

Topo I, a 105 kDa polypeptide, has 4 major domains: the N-terminal domain (1–200

a.a.), the globular core (200–635 a.a.), a small linker domain (636–712 a.a.), and the C-terminal domain (713–765 a.a.). The globular core and the C-terminal domains are responsible for the catalytic activity. The active site of human topo I is a tyrosine residue at position 723.

A number of studies have shown that anti-topo I antibodies recognize multiple epitopes on the entire molecule of topo I, although the ethnic backgrounds and the sites of recombinant topo I fragments used were various. Major epitopes, which are recognized by more than 80% of anti-topo I–positive patients' sera, have been determined in the central part of the molecule – the globular core domain. All these defined epitopes contain the region 484 to 560 a.a. Interestingly, residues 440 to 614 share significant structural similarity with the bacteriophage family of DNA integrases.

The N-terminal domain is highly charged and contains several nuclear-targeting signals. This domain is also antigenic and reactive to more than 70% of autoantibodies against topo I: for example, 1 to 229 a.a., recognized by 74% sera; 1 to 139 a.a., recognized by 74% sera; 74 to 248 a.a., recognized by 86% sera.

The third epitope is located at the C-terminal domain. Sixty to 70% sera reacted to the region 657(8) to 765 a.a. Since the antigenicity of truncated peptide (658–700 a.a.) was reduced to ~40% of anti-topo I antibodies, the C-terminal half of this region is likely to contribute the antigenicity of topo I. Interestingly, the eight residues (717–724 a.a.), including the active site tyrosine723, are also similar to the DNA integrase. In fact, most anti-topo I sera inhibit the relaxation activity of this enzyme *in vitro*.

3.3 T-cell Response

Autoreactive T-cell responses to topo I have been extensively studied by the group of Dr Wright. Kuwana et al. showed by peripheral blood mononuclear cell (PBMC) cultures with recombinant topo I and pokeweed mitogen that HLA-DR-restricted collaboration between topo I–specific T- and B cells is essential for the antibody production in scleroderma patients with anti-topo I antibodies. T- and B-cell epitopes are located in close proximity on the topo I molecule. Autoreactive T cells are of the CD4+ helper phenotype, recognize majorly fragments F5 and F6 (209–386 a.a. and 363–563 a.a. respectively), and express highly restricted T-cell receptor β-chain variable gene fragments (V_β20.1). Surprisingly, these features are almost common in scleroderma patients and healthy individuals. That is, the topo I–specific T-cell responses are detected in healthy individuals with the appropriate HLA-DR alleles. T-cell clones from healthy individuals can also provide help to HLA-DR-matched patients' B cells in producing anti-topo I antibodies through a CD40-dependent mechanism.

The ability to promote anti-topo I autoantibody production is strictly correlated with IL-2 and IL-6 expression by the T-cell clones. Most topo I–specific T-cell clones express both Th1 and Th2 cytokines, and the patterns of cytokine expression are heterogeneous, supporting the concepts that the human T-cell cytokine profile is not controlled by a simple binary switch between two sets of genes, each cytokine gene expression is regulated independently, and synergy between T cells with complementary cytokine production plays a role in regulating B-cell function. According to kinetic studies, it is strongly suggested that

topo I–reactive T cells having a strong helper activity are selectively expanded in patients with anti-topo I antibody. Also interestingly, for autoreactive T-cell responses, antigen forms (native full-length vs fragmented) and cells of antigen presentation (dendritic cell vs antigen-presenting cell in PBMC = monocytes and B cells) are critical. The fact that fragmented recombinant protein strongly induces T-cell responses suggests cryptic epitopes (see Chapter 6) recognized by autoreactive T cells.

4
Scleroderma-associated Nucleolar Autoantigens

4.1
Fibrillarin

Fibrillarin is a 34 kDa protein that derives its name from its localization to both the fibrillar center and dense fibrillar component of the nucleolus. It is associated with U3 and other small nucleolar RNAs (snoRNAs) required for rRNA processing. Kasturi et al. showed, using an immunoblot with recombinant fragments, that antifibrillarin antibodies reacted primarily with epitopes present in the N- (1–80 a.a.) and C- (276–321 a.a.) domains of fibrillarin in addition to a minor epitope at an internal region (149–229 a.a.).

Autoantibodies against fibrillarin can also be induced in H-2^s mice by treatment with mercuric chloride ($HgCl_2$). Immunoprecipitation studies with truncated yeast fibrillarin shows similar recognition of a conserved conformational determinant of antifibrillarin responses in murine $HgCl_2$–induced autoimmunity and human scleroderma. However, the target of the autoantibodies is not a fibrillarin–mercury complex even though a metal–protein interaction does occur. Proteolytic cleavage of fibrillarin following xenobiotic-induced cell death can lead to the generation of novel protein fragments that obtain more appropriate immunogenic activity. These studies by Pollard et al. suggest that cryptic peptides (see Chapter 6) would serve as antigenic determinants for autoreactive T cells.

4.2
PM/Scl Antigen

A nuclear/nucleolar particle termed *PM/Scl* has been shown to immunoprecipitate a complex of 11 to 16 polypeptides ranging from 20 to 110 kDa. The PM/Scl complex is the human homologue of the yeast exosome, which is an RNA-processing complex. In immunoblotting studies, two major antigenic polypeptides have been shown – a 100 kDa antigen (PM/Scl-100) recognized by most anti-PM/Scl sera and a 75 kDa antigen (PM/Scl-75) recognized by around half the sera. According to epitope mapping of PM/Scl-75 by Alderuccio et al., the major epitope was estimated to be present within the C-terminal 160 amino acid residues. Of eight anti-PM/Scl sera, however, only two sera react with the cellular 75 kDa antigen as well as the C-terminal region. Interestingly, three additional anti-PM/Scl sera displayed a weaker reactivity with the entire PM/Scl-75 recombinant protein, suggesting the existence of another epitope in the N-terminal half. By mapping studies of PM/Scl-100 with truncated recombinant proteins, Bluthner and Bautz mapped two autoepitopes on the recombinant PM/Scl-100: one antigenic domain between amino acids 153 to 324 recognized

by all anti-PM/Scl–positive sera, another domain between amino acids 492 to 703 recognized by the minority of sera. Ge et al. identified three antigenic regions; 156 to 312, 507 to 749, and 750 to 882. Using synthetic peptides, Bluthner et al. demonstrated that a cluster of epitopes is located between amino acids 166 and 245 and that the second cluster is located between 672 and 866. Among them, a major epitope is located between 231 and 245, which is suggested to form a local α-helical secondary structure. Recently, anti-PM/Scl antibodies are shown to recognize also other components in human exosome.

5 Molecular Mimicry and Scleroderma Autoantigens

Production of some autoantibodies has been considered to be caused by cross-reactivity between viral or bacterial protein and autoantigen, which were named *molecular mimicry*. The concept of molecular mimicry was first tested in an experimental animal model of autoimmune encephalomyelitis in 1985, and since that time, substantial evidence has accumulated such that it has become the favored mechanism for causing some autoimmune diseases. If the first reaction was initiated by a foreign stimulus, the major epitope would have a similar antigenicity to the true antigen as a reminiscence of the primary immunization. However, recent epitope-mapping studies indicate that none other than the antigen molecule itself is a trigger molecule as for autoimmunity in systemic autoimmune diseases. Maul et al. reported that the sequence spanning 741 to 746 in the C-terminal region of topo I matches a sequence present in mammalian retroviral $p30^{gag}$ core nucleoprotein. However, antibodies reacting to the sequence are shown to be rare in anti-topo I autoantibodies, and topo I fragments containing this sequence were rarely recognized by peripheral blood T cells from anti-topo I–positive patients.

Because the two autoepitopes of CENP-A have been restricted to small peptide regions, its possible molecular mimicry was explored. A variety of autoantibodies has been described in hepatitis B and C for ages and we found that major epitopes of CENP-A, peptides A and B, are homologous to the core antigens of hepatitis B virus (HBV) and hepatitis C virus (HCV). Especially, the HCV core antigen contains a sequence similar to peptide B and the PRRRS sequence that repeats in peptide A. However, the corresponding regions of viruses were not generally recognized by HBV- or HCV-infected sera according to the previous epitope-mapping studies of hepatitis patients. Detailed mapping studies by Mahler et al. showed that the CENP-A major epitope motif (GPXRX) was present in Epstein–Barr nuclear antigen 1. However, the gradual development of ACA in a patient from an antihistone response was not mediated by the molecular mimicry mechanism resulting from an anti-Epstein–Barr virus response.

6 Apoptosis and Scleroderma Autoantigens

A lot of evidence suggests the involvement of biochemical events activated during apoptosis (programmed cell death), such as caspase activation in the generation of particular autoantigens targeted in systemic autoimmune diseases. Selective substrate phosphorylation/association to splicing factors has been seen to be

a crucial event for production of some autoantibodies. During apoptosis, for example, the lupus autoantigens cluster and become concentrated in the surface blebs of apoptotic cells where several of these molecules are specifically cleaved by proteases of the interleukin 1β–converting enzyme family. Lymphocytes are educated not to react against immunodominant epitopes of autoantigens and consequently autoantibodies are not produced. However, the fragmentation of specific autoantigens as a result of apoptosis can generate cryptic epitopes, which may break tolerance to autoantigens.

Casciola-Rosen et al. demonstrated that scleroderma autoantigens (topo I, the large subunit of RNA polymerase II, NOR-90) are fragmented in the presence of reactive oxygen species (ROS) and specific metals, such as copper and iron. They propose that the autoantibody production in scleroderma is induced and driven by cycles of ischemia/reperfusion generating ROS. The observation that scleroderma autoantigens are enriched in nucleoli should be noted since they colocalize with sites of high-affinity metal binding. Fibrillarin can also be fragmented and can acquire high immunogenicity during apoptosis induced by administration of mercury (see Chapter 4.1).

Although a number of autoantigens have been shown to be cleaved by caspases during apoptosis, susceptibility to cleavage by caspases is not considered to be a general feature of autoantigens due to the reasons that (1) caspases during all forms of apoptosis produce identical fragments of autoantigens and (2) several autoantigens (e.g. CENP-B, fibrillarin) cannot be cleaved by caspase. Casciola-Rosen et al. found that several autoantigens are exclusively or preferentially cleaved by Granzyme B, which is a serine protease found in the cytoplasmic granules of cytotoxic T lymphocytes and natural killer cells, and induces apoptosis in target cells during granule exocytosis–induced cytotoxicity. The function of Granzyme B is achieved partly by catalyzing the cleavage and activation of several caspases, as well as through caspase-independent pathways. Also, for scleroderma autoantigens, cleavage by Granzyme B is strongly predictive as shown in Table 2. B-cell epitopes of these antigens are believed not to be hidden in the intact molecule because

Tab. 2 Scleroderma autoantigens cleaved by granzyme B.

Autoantigens	*Cleavage site*
Topoisomerase I	$IEAD^{15}$-F[a]
Fibrillarin	$VGPD^{184}$-G[a]
PM/Scl-100[b]	$VEQD^{252}$-M
CENP-B[b]	$VDSD^{457}$-E
CENP-C	$ITQD^{452}$-E[c], $VGHD^{607}$-E[c], $LESD^{621}$-E[c], $LSPD^{775}$-T[c], $LDND^{804}$-E[c], $VGQD^{888}$-I[c]
PM/Scl-75	$LEND^{188}$-Q[c], $LEPD^{321}$-K[c]
p27 (SSSCA1)	$LDSD^{79}$-V[c]

[a]Cleaved sites are experimentally defined by Casciola-Rosen et al.
[b]Cleavage by Granzyme B was confirmed by Casciola-Rosen et al.
[c]Possible cleaved sites according to the consensus sequences.
As for CENP-A and $HP1^{HS\alpha,\beta,\gamma}$, no consensus sequences are found.

(1) most antibodies do not preferentially recognize cleaved forms, (2) most autoepitopes are the functional sites of antigens, and (3) cleavage sites are not associated with the major epitope region (Tables 1 and 2), although we cannot speculate on conformational change induced by cryptic peptides. Although the preferential autoantibodies against Granzyme B-cleaved CENP-C in scleroderma patients with ischemic digital loss were recently shown, the theory that Granzyme B-generated fragments serve as a source of T-cell antigenic determinants is more relevant as shown in the study of topo I (see Chapter 3.3).

Investigations of early-involvement lesions in scleroderma suggest that apoptosis of endothelial cells, possibly caused by cytotoxic antiendothelial cell antibodies, may occur before the infiltration of lymphocytes. Although a direct role for the antibodies inducing apoptosis *in vivo* remains to be elucidated, the recent report by Lunardi et al. showed that antibodies in scleroderma patients, reacting with the human cytomegalovirus late protein UL94, cause apoptosis of endothelial cells through specific interaction with the cell-surface integrin–NAG-2 protein complex. Other than protein cleavage described above, recent studies showed that, in the case of infection of herpes simplex virus type 1, viral immediate-early protein ICP0 induced degradation of CENP-A and CENP-C by a proteasome-dependent manner. This is one of the cases in which viral infection can induce an altered autoantigen. In order to clarify the pathogenesis of scleroderma, further studies especially to reveal mechanisms of exposure of a cryptic epitope and its reactive T-cell activation are needed.

Bacterial Isolation
This is he separation from a sample of one or more bacterial species. The basis of the separation is ability of these isolates to grown under selective conditions. This selectivity can be physical, chemical or biological in nature.

Bacterial Culture
A particular strain or kind of bacteria growing in a laboratory medium. It is usually assumed that the bacteria is growing in pure culture, without contamination.

Microscopy
The observation of bacteria requires the use of microscopy. A number of methods can be used to enhance the appearance of bacteria under the microscope. Simple or complex stains are widely used.

Population Estimation
Determining the numbers of bacteria present in a sample is often required. A number of techniques can be used including direct microscopic counts, dilution plate counts, absorbance and most probable numbers. Each can give useful estimates of population increases and hence growth rates.

Biochemical Characterization
Microscopic observations rarely allow bacterial identification to the genus level. The metabolic activities and other characteristics of the bacteria are also required. Biochemical characterization of the bacteria assits in the identification of the organism.

This chapter provides essential information to help the researches in the successful culturing of a wide range of bacteria. It includes guidance on the isolation, culturing, microscopic examination, characterization and identification of bacteria.

1 Cultivation of Bacteria

1.1 Introduction

Much of microbiological work depends upon the maintenance of pure cultures of microorganisms. Aseptic technique is largely a matter of commonsense, but the following points should be borne in mind:

- Clean air contains many bacterial and fungal spores, carried on dust particles or in water droplets; any surface exposed to the air quickly becomes contaminated. Instruments that can be sterilized by heating in a Bunsen flame, for example, inoculating loops, can be left exposed, but must be flamed thoroughly before use. Items that cannot be treated in this way, for example, pipettes should be sterilized in wrappings or containers.
- Microbial contamination in the laboratory is most often due to currents of unsterile air. The chief merit of inoculation cabinets therefore lies in the protection they give from draughts. This protection can be supplemented by keeping all windows and doors shut and by cutting down personal movement within the laboratory.

Prior to identification it is often necessary to obtain pure cultures of bacteria growing on plates containing a suitable nutrient medium. Bacteria display many variations of the major nutritional requirements and so the utilizable sources of energy also vary. However, the media for the cultivation of bacteria must contain (1) water; (2) some source of energy, usually as a carbon compound; (3) other essential elements such as N, S, P, K, Na, Mg, Ca, Fe and Cl in balanced proportions. Some bacteria also require vitamins. In preparing the media, chemicals of defined composition are preferred to those of undefined composition. However, since the nutritional patterns of all bacteria are not sufficiently well known, it is often necessary to use substances of unknown composition, for example, peptone. In addition, media are often solidified with complex substances like agar. Most chemicals should be dissolved in distilled or demineralized water. Tap water may contain toxic elements, particularly copper.

Most bacteria can only grow within a restricted pH range, and are usually intolerant of acid conditions. The reaction of the medium must be adjusted so that the final pH after sterilization is between 6.8 and 7.2, unless a different reaction is needed for some special purpose. If a medium contains substances that may become more acid during sterilization, it is usually adjusted to a pH value about 0.2 greater than that required, that is, 7.0 to 7.4. Buffers are often required to facilitate the growth. This is particularly true of media composed of simple compounds or media in which acid-producing bacteria are cultivated.

1.2 Cultures

Liquid media (broths) are distributed in flasks or tubes plugged with nonabsorbent cotton wool or plastic caps. Liquid medium can be solidified with agar (1.0–2.0%). Agar is an extract of seaweed and is a sulfate ester of a linear galactan, though contaminated with other organic impurities. Generally, agar can be regarded as inert. Agar gels liquefy between 96 and

100 °C, but do not set until their temperature has dropped to 42 °C.

Occasionally, it may be necessary to exclude all organic material (including agar) from the media. In this case, silica gel can be used to solidify the medium. $Na_2SiO_3 \cdot 9H_2O$ (13.4 g) is dissolved in 100 mL distilled water. The pH must be adjusted to 10.0 using cation-exchange resin AG50 WX-8 (Bio-Rad Laboratories) under constant mixing. After 30 min, the pH of the resin must be readjusted to 10.0. The resin must then be removed by filtration using Whatman No. 1 filter paper. After the addition of appropriate nutrients for bacterial growth, sterilization is achieved by filtration through a sterile membrane filter (0.45 μm). The pH of the solution is then adjusted to 7.0 using phosphoric acid (5 M). Finally the medium is poured and allowed to gel (40 min at room temperature).

Solid media can be used in a variety of ways:

Slope cultures. Tubes or small bottles containing 6 mL of medium are heated to melt the agar. This is allowed to set in a sloping position, thus increasing the surface area of the medium for the growth of bacteria.

Deep stab cultures. Tubes or bottles containing 10 to 15 mL of solid medium are heated and the molten medium is allowed to cool to 45 °C. While still liquid, the medium is inoculated, mixed well by rotating the tube between the hands, and then allowed to set.

Plate cultures. About 15 to 20 mL of solid medium are needed for each 9-cm petri dish. The medium is melted and cooled to 45 °C and poured into the dish. Hot media must never be poured since water may condense inside the lid. The medium can be inoculated in several ways:

1. The inoculum is first placed in the petri dish and then the medium is poured over. To ensure even distribution of the inoculum, the plate is moved gently with a rotating movement. This method is used when all the bacteria in a measured inoculum are required to grow into separate colonies, for example, a dilution-plate count.
2. Alternatively, the agar can be inoculated by the poured plate or the streak plate methods, which are described below.

1.3 Culture Incubations

Cultures should be incubated at the optimum temperature for growth or for the specific activity being studied. Pathogens and commensal species grow best at body temperature, that is, 37 °C. Soil organisms and plant pathogens are incubated at 20 to 25 °C.

1.4 Types of Media Used for Growing Selected Bacteria

Bacteriological media are frequently classified as complex or defined according to their chemical composition. A complex medium is one that contains such ill-defined substances as yeast or beef extract, while a defined medium can have 10 to 20 different chemicals present, but the identity of each is known. All of the most widely used media are available from a range of supplies, some of which are listed in Appendix 1.

2 Methods of Bacterial Isolation

2.1 Sterilization

Media are usually sterilized after distribution into bottles, tubes, or flasks. Sterile media may be transferred aseptically into previously sterilized containers. Table 1 lists the methods commonly used for the sterilization of media.

2.2 Purification of Bacteria from Contaminated Cultures

Progressive dilution is the basis of isolation techniques. This can be applied as follows:

Poured plate method

- Melt and cool to 45 °C three tubes of an agar medium. Inoculate one tube with one loopful of the suspension and mix well by rotating it between the hands.
- Flame the loop thoroughly and transfer one loopful of the mixture from the first tube to the second. Mix again.
- Repeat for the third tube. Pour the contents of all the tubes into the sterile petri dishes and allow the contents to set.
- The second or third plate should show well-separated colonies after incubation. Distinct colonies can then be picked off and examined. If the suspension is very heavy, initial dilution in sterile saline may have to be made.

The streak plate method. This is a quicker, though less reliable method.

- Prepare a plate of solid medium. Dry the plates for 30 min before use by placing them open with the open sides facing downwards in a 45 °C incubator.
- Mark the plate on the underside into four sectors. With a sterile loop, place a small drop of suspension on the agar at one side of a marked sector near the edge of the dish. Draw this out in a single broad tangential streak.
- Flame the loop, cool it by touching the agar at the end of the dish away from the inoculum and draw a set of

Tab. 1 Common methods of sterilization.

Treatment	*Comments*
Autoclave	Most media can be sterilized by treatment in an autoclave, usually a 15–20 min treatment at a pressure of 1 kg cm^{-2}. This raises the steam temperature to 121 °C
Steaming	Media that cannot be autoclaved (e.g. sugar media) may be sterilized by intermittent steaming. Samples are heated over boiling water in a steamer (85–95 °C) for 15 min on each of 3 successive days. Between treatments the material must be left at a suitable temperature for the growth of endospores
Filter sterilization	It is necessary to sterilize some ingredients separately before use. Heat-labile ingredients (some antibiotics, sugars, and vitamins) are sterilized by filtration through a membrane filter (pore size 0.2–0.45 μm), which excludes bacteria
Dry heat	Dry glassware such as empty flasks, e.g. pipettes cannot be satisfactorily autoclaved and must be sterilized in a hot air oven for a minimum of 2 h at a temperature of 160 °C. All material should be allowed to cool to room temperature before removal from the oven

tangential streaks cutting across the first streak and covering one half of the plate.
- Turn the plate through 90° and continue the process, flaming and cooling the loop between each set of streaks.

After incubation, well-separated colonies should be found along the streak marks. Before deciding that a culture is pure by either method, colonies should be picked off, grown and then reseparated, until all the colonies are the same. Staining must be used as a check on the purity of the final isolations.

2.3 Isolation of Bacteria from Natural Sources

The object of viable counting techniques is to estimate the number of all live organisms in a given sample of material. To do this, a medium satisfying the nutritional requirements of as many bacteria in the sample as possible is required. Other types of viable count and all isolation techniques embody the reverse principles. Here it is necessary to pick out and encourage one type of organism and to prevent or repress the development of the other types. In natural habitats, the organisms that one is isolating may be present only in small numbers. The first step in such cases is thus to obtain an enrichment culture by one or more of three methods:

1. using selective media,
2. using selective conditions of incubation,
3. selective pretreatment of the material.

Several generations of subcultures on liquid, or solid media may be necessary, but the final step will consist of plating out the organisms.

2.4 Use of Selective Media

A completely selective medium allowing the growth of only a single species is not attainable in practice, but media that will discourage all but the required species can be obtained.

Some selective media are also differential. Certain organisms, when grown on them, exhibit distinctive biochemical or morphological characters, which enable them to be recognized easily. This may be very important from a medical point of view, where the range of species concerned is small. Where a large range of species is involved, for example, in soil, differential media cannot be used to separate taxonomic groups, but are useful to distinguish groups concerned with some biochemical process, for example, cellulose decomposition.

Selectivity may be achieved in three ways,

1. by adding something to the medium to discourage the growth of species that are not required,
2. by altering the pH of the medium,
3. by omission of some ingredient required by most bacteria, but not the ones required.

Most bacteria are facultative aerobes, that is, they can grow under aerobic or anaerobic conditions, the latter ability being dependent upon the presence of some substance that can be utilized as a hydrogen acceptor by the species concerned. Some bacteria are obligate aerobes, unable to use anything but oxygen as a hydrogen acceptor. Others are obligate anaerobes, which cannot use oxygen as a hydrogen acceptor. A few bacteria are intermediate, growing best

in low oxygen tensions. These are called microaerophilic bacteria.

Anaerobic forms occur in several families of bacteria. They include several pathogens, for example, *Clostridium tetani*, certain autotrophic bacteria, for example, the purple sulfur bacteria, and some other soil or water bacteria, such as *Desulfovibrio* and *Clostridium*.

During growth, aerobic bacteria tend to utilize all available oxygen and so reduce the medium. Thus, in mixed cultures the oxidation–reduction potential (Eh) of the medium may become low enough to allow anaerobes to develop. This property has also been utilized to grow pure cultures of anaerobic bacteria. Thus, double petri dishes have been cemented together, so that the aerobe in one half uses the oxygen, allowing the anaerobe to develop in the other half.

Pure cultures of anaerobes are usually grown making use of other methods. Steps must be taken to ensure that access of oxygen to cultures is prevented or reducing substances must be added to the medium. Media to be used for the cultivation of anaerobes must be heated at 100 °C for 10 min to drive off the dissolved oxygen and cooled quickly, immediately before use.

2.5 Methods for Anaerobic Cultures

Stab and shake cultures. Many anaerobes can grow in deep stab or shake cultures in glucose agar. This method is particularly useful for microaerophilic species. A seal of liquid paraffin or Vaseline is sometimes advocated to help maintain anaerobic conditions, for example, the Hugh & Leifson fermentation test.

Anaerobe jar culture. If surface cultures are required, the plates or slopes should be placed in an anaerobe jar. This is a glass or plastic jar with a lid that can be clamped down firmly to form an effective seal. Usually a Gas-Pak method is used in which a sachet (to which water has been added) is placed in the jar. The chemical reaction uses oxygen and generates both hydrogen and carbon dioxide. A strip of methylene blue paper acts as an indicator.

Robertson's cooked meat broth. 1 kg of lean meat is minced and simmered with 1 L of water plus 1.5 mL of 1 M NaOH for 20 min, strained and washed very thoroughly with distilled water and partially dried. It is distributed into tubes to form a layer at least 1-cm deep. Nutrient broth is then added to a depth of about 8 cm and the medium is sterilized. The sterilized tissue contains reducing substances that are effective in maintaining anaerobic conditions at the bottom of the tube. The reducing activity of the meat is shown by the pink hematin at the bottom of the tube.

Thioglycollate medium. This is prepared by adding 0.1% (up to 0.4%) thioglycollic acid to the nutrient broth before adjusting the pH. 1% glucose must also be added. Although the medium may be solidified with agar, it is more usual to use a semisolid medium, that is, 0.5% agar. The increased viscosity of the medium prevents the distribution of oxygen (dissolved at the exposed surface), by convection currents. Methylene blue is added to act as an indicator of reducing conditions. A blue-green layer at the surface shows the depth to which oxygen has diffused into the medium. Inocula should be introduced carefully by means of a fine pipette, to the bottom of the tube.

3
Microscopic Examination of Bacteria

3.1
Introduction

Since most bacteria are not more than 2 to 4 μm in length and 0.3 to 1.0 μm in width, any examination of bacteria involves the use of high magnifications. To attain these magnifications use is made of oil immersion lenses with focal lengths of 2 mm or less. Care must be taken when using them as the working distance between the lens and object is very small. Always locate bacteria on a slide with the ×10 and ×40 lenses before preparing to examine them under oil.

3.2
The Examination of Living Unstained Bacteria

The most useful and frequently adopted method of examining live bacteria is the "hanging drop" preparation.

- A small piece of plasticine should be rolled out until its length equals the circumference of the cover slip.
- The plasticine is placed on the slide in the form of a ring or a square.
- With a wire loop, a small drop of the bacterial suspension is placed on a cover slip laid on the bench.
- The slide is then inverted, the plasticine pressed gently on the cover slip and the slide quickly turned over again, leaving the suspension as a "hanging drop."
- The slide should then be examined under the ×10 objective, and with the edge of the drop focused. Swing the ×40 objective lens into position and adjust the microscope. The method is used to detect motility, but this should be distinguished from the Brownian movement that is exhibited by any small particles suspended in a liquid. Examination of these preparations under oil is difficult since currents of liquid are set up during focusing.

Phase contrast microscopy is the easiest method for examining hanging drops or even ordinary cover slip preparations. Bacteria appear as dark objectives against a pale background. The method, utilizing special objectives and condensers, depends upon the change of phase of the white light as it passes through objects with different refractive indices.

3.3
The Measurement of Bacteria

The measurement of bacteria is achieved by using a stage micrometer, together with a micrometer eyepiece. On the stage micrometer, a scale graduated in hundredths of a millimeter is engraved. In the micrometer, the eyepiece is a second graduated scale, which may be focused with a movable eyepiece lens.

- The micrometer eyepiece is inserted into the microscope and the stage micrometer is focused.
- The number of divisions of the eyepiece scale corresponding to a definite number of stage micrometer scale divisions is determined.
- The stage micrometer is removed, the object to be measured is focused, and the number of divisions of the eyepiece scale, which cover the object, is noted.

3.4
Methods of Staining Bacteria

The preparation of films for staining

- A drop of the bacterial suspension should be transferred to a clean grease-free slide with a sterile loop. The drop

should be small, it should be spread evenly, and allowed to air-dry.
- Because of their small size, bacteria dry without great distortion and so the only fixation required is to pass the slide quickly two or three times through the Bunsen flame at this stage.

General staining principles. Dyes may be of the acidic or basic type, the former owing their colored properties to an anion, the latter to a cation. Basic dyes have greatest affinity for the nuclei of cells because of the acidic nature of the nuclear material. Acid dyes have greatest affinity for the cytoplasm.

The chemicals used in the preparation of staining solutions are frequently variable in composition. Variations of this type and those of technique make it essential to use proper controls. Smears of known positive and negative organisms should always be prepared.

Differential stains. There are a number of more complex staining procedures designed to demonstrate different parts of the bacterial cell, and different types of bacteria.

Gram's method. Some bacteria when treated with para-rosaniline dyes and iodine retain the stain when subsequently treated with decolorizing agents such as alcohol or acetone. Other bacteria lose the stain. This property is used to distinguish two types of bacteria, gram-positive and gram-negative forms. Gram-negative forms, which are those that lose the stain on decolorization, can be made visible by using a suitable counterstain. It is known that the stain plus the iodine react with the RNA fraction of the cytoplasm and form a colored, alcohol-soluble substance. Gram-positive forms have cell walls (~95% peptidoglycan) that prevent the ''leaching out'' of the stain from the cytoplasm with alcohol while the gram-negative ones (~5% peptidoglycan) do not. A useful form of the gram's stain is Hucker's modification.

- The smears are stained with ammonium oxalate crystal violet solution for 1 min. Ammonium oxylate crystal violet is prepared using ammonium oxylate 0.8 g, crystal violet 2.0 g, ethyl alcohol 20 mL and distilled water 80 mL.
- The slides are washed in tap water for 2 to 3 s and then immersed for a further minute in Lugol's iodine solution. Lugol's iodine is prepared by adding iodine 1.0 g, potassium iodide 2.0 g, distilled water 300.0 mL.
- The slides are washed again and blotted dry.
- This is followed by treatment with 95% *ethanol* for 30 s. The slide should be gently rocked during this step.
- After further quick washing with water and blotting, the slides are counterstained with *safranin solution* for 10 to 30 s. Safranin solution is prepared by adding safranin, (2.5% solution in 95% ethanol), 10 mL and distilled water 100 mL.
- The preparation is washed, blotted, and examined under the oil immersion lens. Gram-positive organisms will be stained purple and gram-negative organisms will be stained red. Endospores remain unstained. Organisms with known reactions should be used as controls on the same slide.

Acid-fast staining (Modified Ziehl–Neilsen method). Certain bacteria, for example, *Mycobacterium*, cannot be stained by ordinary aniline dyes except by using strong solutions with phenol and possibly heat. Once stained, these bacteria resist decolorization by acids and are called *acid-fast bacteria*. This stain is used

primarily to detect *Mycobacterium tuberculosis*, but other species of *Mycobacterium* are acid-fast to some extent and can be destained by following the acid treatment with 95% alcohol.

- The dried film is stained with Ziehl's carbol fuchsin for 5 min, applying enough heat to give steam. Do not let the slide dry out. Ziehl's carbol fuchsin is prepared by dissolving basic fuchsin (0.3 g) in 10 mL of ethanol. This is then added to phenol (heat melted crystals), 5 mL dissolved in 95 mL of distilled water. The solution must be mixed, allowed to stand for a few days, and filtered prior to use.
- The slide is washed.
- After removing the excess water, the slide is treated with a decolorizing solution (hydrochloric acid, 3.0 mL; ethyl alcohol, (95% v/v) 97 mL).
- The film is immediately washed with water and the decolorization repeated until the film appears faintly pink.
- The organisms are counterstained with 0.3% aqueous methylene blue for 20 to 30 s, washed and blotted dry. Acid-fast organisms retain the red stain while others are stained blue. Endospores of *Bacillus* are also acid-fast (see below).

Spore staining (Conklin's method). Spores are not so readily stained by Gram's stain as is the rest of the cell. Thus, frequently they are observed as clear areas in the center of otherwise stained cells. This is because the spore is rather more acid-fast than the rest of the cell, that is, it does not stain easily, but once stained does not release the stain readily. Perhaps the easiest method of staining spores is by Conklin's method.

- Smears are prepared and fixed in the normal way. The slide is stained with 5% aqueous malachite green for 5 min, heating the slide gently over a low flame until it steams. Aqueous malachite green is produced by adding 5 g of malachite green to 100 mL distilled water.
- After washing the slide for 30 s, the smear is counterstained with 5% aqueous mercurochrome or 0.25% aqueous safranin (10 mL 2.5% safranin solution in 95% ethanol added to 100 mL of distilled water) for 30 s.
- The slide is then washed and blotted dry. Under oil, the spores are stained green and the rest of the cell is stained red.

4
Estimation of Population Sizes of Bacteria

4.1
Bacterial Biomass Measurement

Biomass is the dry weight of bacterial substance per mL of a suspension and can be determined directly provided that the suspension contains no foreign matter.

A sample of culture is treated with formalin (to give a final concentration of 1% v/v) and centrifuged in a weighed tube. The deposit is washed with 0.85% w/v saline +1% formalin and then in 0.05% saline and finally in distilled water. The deposit is dried to constant weight at 105°, placed in a desiccator over phosphorus pentoxide and allowed to cool, and then weighed in a balance (previously dried atmosphere with silica gel).

4.2
Turbidometric Estimations

Where large numbers of determinations are to be made, for example, in making growth curves, turbidometric estimations can be made. These are meaningless,

however, unless translated into terms of cell concentration (viable or total counts), but the relationship between turbidity and cell concentration is different for each different species. Turbidity readings obtained for a series of dilutions of a known number of organisms should be plotted as a calibration graph.

4.3 Theory of Bacterial Growth

Logarithmic growth. The growth of a bacterial culture undergoing binary fission is expressed by the equation,

$$x = x_o 2^n$$

where $x =$ the final number of organisms, x_o the initial number and n is the number of generations.

If n generations are produced in time t, then

$$g = \frac{t}{n} \text{ and } n = \frac{t}{g}$$

where $g =$ the generation or doubling time. Thus

$$x = x_o 2^{t/g}$$

and

$$\ln x = \ln x_o + \ln 2 \frac{t}{g}$$

This is usually written in the form

$$\ln x = \ln x_o + \mu t$$

where $\mu = \ln 2/g = 0.6931/g$.

μ represents the number of e-fold increases in cell numbers that have occurred in time t.

If the equation

$$\ln x = \ln x_o + \mu t$$

is differentiated, it becomes the familiar growth equation

$$\frac{dx}{dt} = \mu x$$

which may be stated as the rate of growth of the population is proportional to the initial number of organisms present.

4.4 Counting Methods

Counts may be used to determine the number of organisms in a sample and these counts can be converted to estimates of biomass if suitable conversion factors are known.

Total counts. Total counts include the various methods of estimating the total number of bacteria per unit volume or weight of a sample, without distinguishing between viable and nonviable organisms.

Counting chambers. The number of bacteria per mL of a suspension can be determined by means of a counting chamber. The best form of a counting chamber is the Helber cell, but a hemocytometer is still useful. Suspensions of pathogenic or motile bacteria should be inactivated before they are counted, by heating for 1 h at 56 to 60 °C.

- Prepare a dilution that will give an average count of about 20 bacteria per small square, if necessary, examining a drop of undiluted suspension to decide the dilution. The following method is suitable unless extreme accuracy is needed. Measure out 0.5 mL of suspension into a small tube and add an equal volume of diluent (formol saline; 0.5% formalin in 0.9% sodium chloride solution is a suitable diluent) to make a twofold dilution. Mix well by drawing up and down several times in the pipette

and then transfer a measured volume to a second tube. Wash the pipette out with a diluent and add an equal volume of diluent to this second tube. Repeat making further 2-fold dilutions to give a series of 4-fold, 8-fold, 16-fold dilutions of the original suspension to the required degree.

- A few drops of methylene blue may be added to the diluent to make the bacteria more easily seen.
- Place a No. 1 coverslip on the slide and then exactly fill the chamber (not the ditches) with the suspension using a fine pipette.
- Find the grid under the low power, cutting down the light intensity if necessary, and use the ×40 objective for counting. Oil should not be used since it causes sagging of the coverslip and a consequent change in volume of the liquid.
- Count the number of organisms per small square that cover all planes of focus, in 20 squares taken diagonally across the grid. Repeat with a second mount and if time allows, with a third. At least 1000 cells should be counted. The more organisms that are counted, the more accurate is the estimate.
- If cells lie on the lines of the grid, only those on two sides of the square should be counted. All the component cells in small clumps of completely separated cells should be counted as single individuals.
- From the number of organisms per small square, the number per mL of the suspension is calculated. The volume of liquid lying over each square is given on the slide. In a Thoma hemocytometer, the depth of the chamber is 0.01 cm and the area of each small square is 0.000025 cm^2, hence, the number of bacteria per milliliter of the suspension is the average number per small square $\times 4 \times 10^6 \times$ the dilution factor.
- In the Helber cell, the depth of the chamber is 0.002 cm, and the area of each small square is 0.000025 cm^2. Consequently, the number of cells per milliliter is the number per small square $\times 2 \times 10^7 \times$ the dilution factor.

The direct smear method. A known volume of bacteria in suspension is spread over a defined area of a microscope slide, stained, and counted. A variety of differential stains can be used, for example, methylene blue.

- Transfer 0.01 mL of the suspension to a 1 cm^2 area of a microscope slide.
- Allow the slide to dry at room temperature.
- Stain in a damp chamber for 5 min with the following solution (1.3 mL, 0.5 M carbonate–bicarbonate buffer, pH 9.6; 6.0 mL, 0.001 M phosphate buffered saline, pH 7.1; 5.7 mL, 0.85% physiological saline, 5.3 mg crystalline Fluorescein isothiocyanate (FITC)).
- Wash gently but thoroughly in water and blot dry. Observe with a fluorescence microscope.

Viable counts. These methods aim at estimating the number of bacteria capable of growth and multiplication in the material. Aseptic methods must be used throughout.

Making dilutions. In all these methods, the preparation of dilutions is the first step. A weighed amount or measured volume of the material being examined is suspended in a known volume of sterile diluent, mixed well by shaking and further dilutions are made from this.

The diluent used is most important. Sometimes the natural milieu that is,

seawater or river water is used, but more often sterile quarter-strength Ringer's solution is recommended (NaCl, 9 g; KCl, 0.42 g; $CaCl_2$, 0.48 g; NaH_2CO_3, 0.2 g; water, 4 L). A 0.1% peptone solution may also be used as a diluent.

- The required number of tubes containing 9 mL diluent are prepared with a 1-mL sterile blow-out pipette, 1 mL of the sample is added to the first tube.
- With a fresh pipette tip, the liquid is mixed and 1 mL of this 1/10 dilution transferred to a second 9 mL of diluent.
- Repeat until the sample is diluted sufficiently. The number of dilutions needed will depend on the material concerned, only the two or three highest being used.

The dilution-plate method and the spread plate method. Tenfold dilutions are prepared as described above.

- With the pipette used for mixing the dilution, 1 mL of this dilution is placed in each of three or more sterile petri dishes; then after making the next dilutions, 1 mL of this is treated in the same manner and so on until a range of dilutions is plated (usually 3).
- After mixing the dilutions, 15 or 20 mL of an agar medium, previously melted and cooled to 45 °C, is added to each plate and an even distribution is ensured.
- When set, the plates are incubated at the required temperature. After incubation, dilutions where the plates show more than 300 or fewer than 30 colonies are discarded. Errors due to overcrowding or due to sampling make these counts unreliable. Thus only one set of plates will actually be counted if tenfold dilutions are used.
- The inoculum may, as an alternative, be spread over the surface of prepared plates of agar. Usually an inoculum of 0.1 mL is then used and the agar is dried to remove surface water. The inoculum is spread with a sterile glass spreader.

The membrane filter method. This method is used for water samples in which only a few organisms are present. It depends upon the concentration of the inoculum rather than the dilution.

- Sterile cellulose acetate membranes (pore size ~0.45 μm) are placed in a sterilized filter holder.
- A known volume of the fluid is passed through the filter.
- This filter is then laid on a thin layer of the medium in a petri dish and incubated. Bacteria held in the filter develop into colonies that can be counted. Difficulty is often experienced since the even distribution of the colonies cannot be ensured. By using suitable media, particular groups of organisms can be selected.

The "Most Probable Number" method. As well as being economical in time and materials, this method can be used where the plate count cannot, for example, with materials that contain species that form "spreading" colonies on agar or where it is desired to determine numbers of a particular group that is sparsely represented in material with a mixed bacterial flora.

A series of tenfold dilutions are prepared, so that when 1 mL samples of the highest dilution are inoculated into a suitable medium, very few if any bacteria are likely to grow. Thus, if a suspension contains 5×10^9 bacteria per mL, 1 mL of a 10^{-9} dilution would contain 5 organisms, and most or all tubes of medium would

show growth. In a 10^{-12} dilution, all 5 tubes of medium would probably show no growth as there would be only 1 organism per 200 mL.

- Transfer 3 (4 or 5 if possible) replicate 1 mL samples of each suitable dilution to tubes of liquid or plates of solid medium and incubate. A greater range of dilutions (usually 5 or 6) is required in this method, unless the result can be predicted accurately.
- After incubation, record the presence or absence of growth in the recovery cultures.
- Statistical tables, for example, McGrady tables have been compiled, enabling the most probable number of organisms per milliliter of the suspension to be determined. The following example of a McGrady table has been computed for a dilution factor of 10, and for 5 replicate tubes inoculated from each dilution of culture (Table 2).

The entries in the table are the number of turbid tubes observed after inoculation of the same volume from any three successive tenfold dilutions. The stated MPN is the estimated mean viable count per inoculum taken from the most concentrated of the three dilutions being considered.

5 Characterization of Bacteria Using Biochemical and Cultural Tests

5.1 Introduction

Because bacteria are small, morphological characters have never proved satisfactory

Tab. 2 Values of the Most Probable Number (MPN) for 5 tubes inoculated from each of 3 successive 10-fold dilutions.

Significant number Numbers of replicate tubes showing turbidity at 3 successive dilutions			*MPN*	*Significant number Numbers of replicate tubes showing turbidity at 3 successive dilutions*			*MPN*
0	1	0	0.18	5	0	0	2.3
1	0	0	0.20	5	0	1	3.1
1	1	0	0.40	5	1	0	3.3
2	0	0	0.45	5	1	1	4.6
2	0	1	0.68	5	2	0	4.9
2	1	0	0.68	5	2	1	7.0
2	2	0	0.93	5	2	2	9.5
3	0	0	0.78	5	3	0	11.0
3	0	1	1.1	5	3	1	11.0
3	1	0	1.1	5	3	2	14.0
3	2	0	1.4	5	4	0	13.0
4	0	0	1.3	5	4	1	17.0
4	0	1	1.7	5	4	2	22.0
4	1	0	1.7	5	4	3	28.0
4	1	1	2.1	5	5	0	24.0
4	2	0	2.2	5	5	1	35.0
4	2	1	2.6	5	5	2	54.0
4	3	0	2.7	5	5	3	92.0
–	–	–	–	5	5	4	160.0

for the delimitation of species, although in certain cases, it is possible to assign the organisms to families and sometimes to genera. Other characters have been used therefore, to enable more precise classifications of organisms to be made. Perhaps the most widely used tests, however, have been those designed to demonstrate the biochemical and physiological characteristics of microorganisms. The biochemical methods used fall into four groups:

1. Mineral growth requirements and substrate utilization.
2. Detection of metabolic end products.
3. Identification of characteristic compounds, for example, enzymes, gums, and toxins.
4. Resistance and sensitivity to chemicals, for example, antibiotics.

5.1.1 Minimal Growth Requirements and Substrate Utilization

Nutritional studies. It is often useful to know something of the nutrition of a particular bacterium, from the point of view of both taxonomic and cultural studies. It is important to obtain information on the relation of bacteria to nitrogen sources and growth factors. Growth of bacteria with an inorganic nitrogen source can be detected in the Ayer, Rupp, and Johnson's medium: $NH_4H_2PO_4$, 1.0 g; KCl, 0.2 g; $MgSO_4.7H_2O$, 0.2 g; glucose, 10.0 g; water, 1 L. The pH should be adjusted to about 7.0. Several serial subcultures should be attempted in this medium before recording growth as positive since the inoculum may carry over organic nitrogen and growth factors. Further nutritional studies can be made by replacing sources of nitrogen or growth factors in this medium with others. If growth is obtained in the basal medium, all subsequent tests can be carried out using this medium with the particular substances under investigation substituted, for example, in fermentation tests. If no growth is recorded, peptone media must be used as a basis for growth.

Effects of environment. The relation of organisms to free oxygen and pH also fall into this group of tests. These relationships can be elucidated by methods outlined earlier.

Utilization of organic acids. Some bacteria are able to utilize salts of certain organic acids as sole carbon sources. Pathogenic species, which are nutritionally exacting, are less likely to be able to do this, while many of the less exacting soil and water forms can. Thus, while the soil coliforms can utilize citrate, intestinal coliforms cannot, for example, *Escherichia coli*, a commensal in the animal intestine.

Koser's citrate medium is a mineral medium with 0.2% anhydrous sodium citrate as the sole carbon source. Bromothymol blue is usually added to assist in detecting slight growth, by the alkaline reaction produced. Other organic acids can be detected in a similar way, but a lower concentration, for example, 0.1% should be used for the more toxic acids, that is, formic and oxalic acids. The mineral medium most frequently used is KH_2PO_4, 1.0 g; $MgSO_4 \cdot 7H_2O$, 0.2 g; $Na(NH_4)HPO_4 \cdot 4H_2O$, 1.5 g; distilled water, 1 L.

5.1.2 Detection of Metabolic End Products

Indole. Indole is produced by some bacteria from the amino acid tryptophan. A tube of peptone water is inoculated and samples of the culture are tested

at intervals with Ehrlich's reagent (2% para-dimethylaminobenzaldehyde in 95% alcohol). 1 mL is added to the culture and concentrated HCl is added drop by drop until a red zone appears between the alcohol and the peptone solution. No more than 0.5 mL acid is needed. If the colored pigment is soluble in amyl alcohol or chloroform it can be considered to be indole.

Hydrogen sulfide. Hydrogen sulfide may be produced from sulfur-containing amino acids, for example, hydrogen cystine present in peptone. A test for hydrogen sulfide production can be combined with the above test. When the peptone water is inoculated, a filter paper strip impregnated with a saturated lead acetate solution is inserted between the plug and the tube, taking care to keep it dry. If hydrogen sulfide is produced, the paper will become blackened.

Some bacteria also reduce inorganic sulfur compounds. A chemically defined medium containing a sulfur compound, for example, sulfate, or thiosulfate, can be used instead of peptone water. Only organisms that can utilize inorganic nitrogen can be tested in this way.

A number of special media containing iron salts and a source of sulfate can also be used, for example, Kligler's iron agar. Hydrogen sulfide production is recognized by blackening of the medium.

Acetyl methyl carbinol – The Vosges–Proskauer (VP) test. Acetoin or acetylmethylcarbinol can be produced from glucose via pyruvic acid. Two enzymes are necessary for this to occur, that is, pyruvate enzyme and acetolactic decarboxylase. Acetoin may be reduced to 2.3 butanediol and so give a negative result. Sensitive tests should therefore be used to detect acetoin.

The normal method of detection is to oxidize acetoin to diacetyl, which reacts with guanidine residues in the medium to give a cherry red color. The medium used usually contains 0.5% glucose, 0.5% peptone and 0.5% K_2HPO_4 in distilled water. To prevent reducing conditions from developing, fumarate is sometimes added as a hydrogen acceptor or else glucose is replaced by pyruvate.

- After 3 days of incubation, a 2 mL sample of the culture fluid is tested by adding about 5 mL of 40% KOH and a trace of creatine, shaking vigorously and allowing it to stand for up to 60 min. The culture is positive if a cherry red color develops.

Methyl red test. In the examination of coliform bacteria, the VP Test is carried out at the same time as the methyl red test. The latter determines the hydrogen ion concentration produced in a definite time and in a specific medium. The glucose–phosphate medium described above must be used and not a modification of it.

- The culture is tested after 3 days at 30 °C.
- To one part of the culture is added a 0.4% solution of methyl red (1 drop per mL of culture). A magenta red color is positive, a yellow color is negative.

Reduction of nitrates. Certain organisms are capable of reducing nitrate to nitrite and even to nitrogen or ammonia.

- The organism under test is grown in peptone water containing 1% potassium nitrate.
- After incubation, the culture fluid is divided into three portions.
- One portion is tested by adding a few drops of sulfanilic acid reagent followed by a few drops of α-napthylamine reagent (Griess' reagents I and II). A red color indicates the presence

of nitrite. The production of free nitrogen may be detected by allowing it to collect in a Durham tube.

- A second portion of the fluid may be tested for ammonia with *Nessler's reagent*, but since many organisms produce ammonia from peptone, the result must be interpreted with care. [A sample of uninoculated medium should also be tested since some peptones give a positive reaction (i.e. an orange/brown precipitate) with Nessler's reagent].
- If no nitrite has been detected, the third portion of the culture should be tested for residual nitrate for it is possible that all the nitrate will have been converted first to nitrite and then to nitrogen or ammonia. To do this, add a small quantity of zinc dust. This will reduce the residual nitrate chemically to nitrite and this can then be tested for as shown above. The interpretation is as follows.
- *If nitrite is then +, it follows that the bacterium did not reduce nitrate to nitrite; rather it was the Zn dust that reduced it*. If the test on the third portion is negative for nitrite, it follows that all the nitrate had been reduced to another product via nitrite by bacteria and thus the bacterium will be recorded as a positive nitrate reducing organism.

Fermentation tests – Hugh and Leifson's method. Certain carbohydrates that is, sugars, alcohols, and glucosides are attacked and produce quantities of acid and/or gas. It is also important to know which acid and which gas are produced, that is, 2 keto-gluconic acid, propionic acid, lactic acid and so on. Generally speaking, simple tests for detecting the nature of the acids are lacking and so results are most frequently recorded as no acid, acid or acid plus gas. One of the most convenient tests for this purpose is that of Hugh and Leifson.

- A semisolid agar medium is tubed to a depth of 4 cm, two tubes being required for each culture and for each sugar tested. The formula for this medium is as follows:

Peptone	2.0 g
Sodium chloride	5.0 g
Dipotassium hydrogen phosphate	0.3 g
Bromothymol blue (1% aqueous solution)	3.0 mL
Carbohydrate	10.0 g
Water	1.0 L
pH	7.1

  The bromothymol blue is dissolved in water and 3.0 mL of a 1% solution added to each 1000 mL of medium. Alcoholic solutions of indicators should not be used as acid may be produced from the alcohol. For critical studies, the carbohydrate should be sterilized separately and added to the otherwise complete sterile medium.
- After inoculation, one of the pairs of tubes is covered by a layer of sterile melted Vaseline to a depth of 2 cm.
- Several types of reaction may be observed. *Fermentative organisms*, which phosphorylate glucose and then split it into 2 triose molecules before forming acid will produce an acid reaction in both tubes (or the sealed tube only). *Oxidative organisms*, which convert the aldehyde group to a carboxyl group in glucose to form gluconic acid will produce an acid reaction in the open tube only, leaving the sealed tube unchanged. The acid

reaction produced by oxidative organisms is apparent first at the surface and extends gradually downward into the medium. Organisms that oxidize glucose but do not ferment it have never been observed to ferment any other carbohydrates and so the sealed tube can be omitted when testing the other sugars.

Production of aesculetin from aesculin. Hydrolysis of aesculin is shown by the production of blackening in the following medium. Peptone, 10.0 g; aesculin, 1.0 g; ferric citrate, 0.5 g; water, 1 L; agar, 1.2 g.

Levan production. Many bacteria, for example, plant pathogens, are characterized by an ability to produce levan polysaccharides from sucrose. Such compounds may also be produced by soil bacteria and help in maintaining soil crumb structure. This may be detected on a plate of nutrient agar containing 5% sucrose, poured and a channel cut in the agar. This channel is filled with the same medium with 0.1% aniline blue in it. Polysaccharide producing organisms attract the dye toward them while others remain colorless. The inoculum is usually added in two ways; as streaks to the left of the channel and as individual spaced colonies to the right of the channel.

5.1.3 Biochemical Examination of Anaerobic Bacteria

For tests requiring plate cultures, anaerobic jars should be used for incubation, but many of the tests can be carried out without this apparatus, merely by slightly modifying the media.

1. The media may be rendered semisolid by adding 0.5% agar.
2. Fermentative metabolism can be demonstrated by sealing cultures with Vaseline.

5.1.4 Rapid Testing Methods

Analytical Profile Index (API) test strips. API test strips, produced by Bio Mérieux SA, France, may be used to obtain test results quickly. These consist of a series of miniature cupules on a molded plastic strip, each of which contains a sterile dehydrated medium in powder form. Addition of water containing a bacterial suspension simultaneously rehydrates and inoculates the medium. A rapid reaction is obtained because of the small volume of medium and the large inoculum used. Reactions are evident from color changes of indicator chemicals either with or without addition of further reagents. These changes occur after incubation of the strip in a small, humidified, plastic chamber. A range of strips is available containing between 20 and 50 tubes with cupules. These can be used to identify specific groups of organisms, for example, members of the Enterobacteriaceae, staphylococci, anaerobes, lactic acid bacteria, streptococci, and clinical yeasts.

Enterotube II system. The basic philosophy of the Enterotube II system is the same as the API system. The system provides ease, speed, and low cost in the identification of gram-negative Enterobacteriaceae. The system consists of a single tube containing 12 compartments, each containing a different agar-solidified culture medium. Compartments that require aerobic conditions have small openings that allow in air. Those requiring anaerobic conditions have a layer of paraffin wax. There is a self-enclosed inoculating

needle. This needle can touch an isolated bacterial colony and is then drawn through the 12 compartments, inoculating the test media. Fifteen standard tests are performed. After 18 to 24 h of incubation the color changes that occur in each of the compartments are recorded. Interpretation of the results is determined using a five-digit code obtained from the results. A differential chart, supplied by the manufacturer, or a computer-based program, (ENCISE) Enterobacteriaceae numerical coding and identification system for Enterotube can be used.

5.2 Cultural Characteristics

In addition to the morphological and biochemical characters, it is essential to record the appearance of bacterial colonies under defined conditions, for example, on specific media as agar streak plates, gelatin stabs, and in broth culture. The shape and structure of colonies can be described as shown in the figure below:

Keywords

C-period
The time for a round of DNA replication, from initiation at the origin to completion at the terminus. In *Escherichia coli*, the C-period, for cells growing between 20 and 60 min doubling times, is a constant of approximately 40 min.

D-period
The time between termination of DNA replication and cell division. In *Escherichia coli*, the D-period, for cells growing between 20 and 60 min doubling times, is a constant of approximately 20 min.

Multiple Forks
The situation that occurs when initiation of DNA replication occurs on a molecule that has not finished its previous round of replication; there are forks upon forked material.

Cytoplasm
The collective name for the numerous components of the cell that are not associated with either the cell wall or the genome. It is composed of the small molecules such as ions, metabolites, and cofactors, macromolecules such as soluble enzymes, tRNAs, mRNAs, and higher complexes such as ribosomes.

Peptidoglycan
The stress-bearing, presumably shape-maintaining, layer of the bacterial cell wall. It is composed of glycan chains cross-linked with amino acids.

Cell Membrane
The lipid-containing structures that lie adjacent to the peptidoglycan layer. Some cells have a single membrane layer, while others have two different membranes, an outer and an inner membrane.

Segregation
The distribution of cell material from the dividing mother cell into the two daughter cells. Different cell components may have different segregation patterns.

Origin
A sequence on a chromosome or a plasmid where normal replication of DNA initiates.

Terminus
A point or region on a chromosome or plasmid where a round of replication terminates.

Bidirectional Replication
Replication of DNA with two replication forks proceeding in opposite directions away from the origin of replication.

GC-skew
The excess (or deficit) of G residues over C residues within a single strand of DNA. While G = C in a double helix, an individual strand may have an excess of G within a region or an excess of C residues within a region.

FtsZ Ring
The ring of synthesis of the pole region during pole formation.

A dividing bacterial cell must, on average, have precisely twice as much of everything found in a newborn cell. How does a bacterial cell ensure that all cell components are duplicated between divisions, and how does a cell ensure that it does not divide prior to duplicating all of its components? These questions have been investigated by studying biosynthesis of cell components during the division cycle. Cell cytoplasm increases uniformly and exponentially during the division cycle. There does not appear to be any cell-cycle-specific syntheses of cytoplasmic components during the division cycle of a well-studied bacterium such as *E. coli*. DNA replication is initiated at a specific time in the division cycle when the cell mass per chromosome origin reaches a particular value. Once initiated, DNA replicates at a constant rate such that the time between initiation and termination of replication is relatively independent of the growth rate. The time between termination of replication and cell division is also relatively constant. High-copy plasmids replicate throughout the division cycle and low-copy plasmids replicate at a particular time during the division cycle according to rules similar to that for initiation of chromosome replication. The cell surface grows in response to the increase in cell mass so that the turgor pressure inside the cell, and the cell density, are constant during the division cycle. At division, the components of the cell are segregated to the two daughter cells. The cytoplasm segregates randomly, the DNA segregates stochastically but nonrandomly, and the peptidoglycan segregates in a manner consistent with the fixed location of the synthesized peptidoglycan. The key ''events'' during the division cycle are the initiation and termination of DNA replication and the initiation and termination of pole formation. There do not appear to be other cell-cycle-specific events or syntheses during the division cycle that are related to the regulation of the division cycle.

1
Growth of Bacterial Cultures

1.1
The Classical Growth Curve

For almost a century (since Buchanan, 1918), the classic growth curve has been used as a description of the pattern of bacterial growth. An overgrown culture is diluted into fresh medium and at first there is a ''lag'' phase, experimentally defined as a period before viable cell number begins to increase. Then cell numbers begin to increase and the culture enters the ''log'' phase. The log phase is the period of exponential increase in cell number. Although the cells during this period of steady state cell number increase are growing exponentially, the cells are generally referred to as being in ''log'' phase because of the usual plotting of cell number on semilogarithmic coordinates. During the log phase, plotting cell number increase on semilogarithmic paper yields a straight line that can be used to determine the doubling time of a culture. After the cells grow to higher concentrations, cell growth slows as the cells enter the stationary phase. Cell growth then ceases. Finally, if a culture is studied long enough, cells begin to lose viability or the ability to form colonies, and the culture enters the death phase.

During these phases, there are changes in cell sizes. The initial cells in the overgrown culture are small, cell size increases during the lag phase, cells are largest during the log phase, and then cell size decreases as cells enter the stationary phase. This classical view of the way in which cells grow is really a special case of the phenomenon of changes in cell size with changes in growth rate.

1.2 Bacterial Growth at Different Growth Rates

It is possible to grow a given bacterium in cultures at a wide range of growth rates. For example, it is possible to grow *E. coli* with a 300-min interdivision time with serine as the sole source of carbon, and a little faster than 20-min interdivision times in various complex broths available for bacterial culture. By varying the medium composition, it appears that any possible growth rate is allowable, so that there is a continuous range of allowable growth rates between the extremely slow and the extremely fast.

When bacteria are grown at a given temperature in different media at a number of different growth rates, a regular pattern of cell composition and cell size is observed. The faster a cell grows (richer medium) the larger the cell and the more the DNA, RNA, protein, and other components per cell (Fig. 1). When cell components are accurately measured, it is found that the material per cell increases exponentially as a function of the reciprocal of the doubling time (i.e. growth rate, as a shorter doubling time indicates a faster growth rate).

1.3 The Shift-up

During a shift-up from a slow growth medium (e.g. minimal medium, in which cells are small) to rapid growth in a rich medium (e.g. nutrient broth, in which cells are larger), there is a regular pattern of change in cell size and composition. Immediately after the shift-up, there is a rapid change in the rate of RNA and protein synthesis to the new rate of increase. There is a slower change in the rate of DNA synthesis. There is a delay before there is any change in the rate of cell number increase. Because of

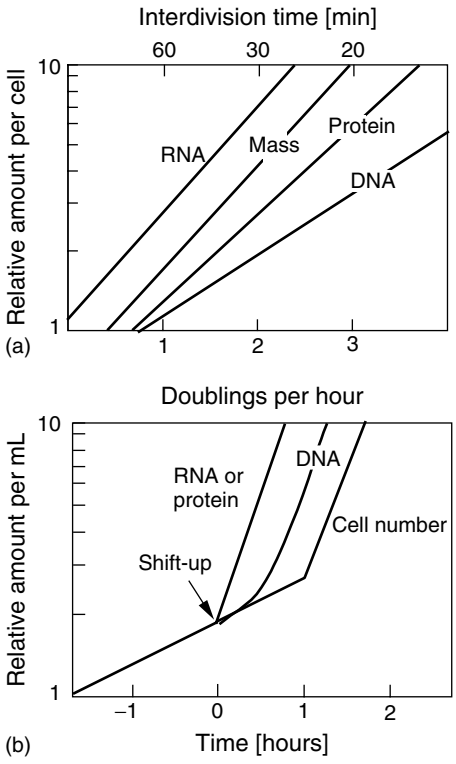

Fig. 1 (a) Composition of bacteria as a function of growth rate. (b) Synthesis of cell components during a shift-up from minimal medium to faster growth in richer medium.

the dissociation of mass increase and cell number increase, the average cell size increases during this first part of the shift-up. After a period of time, there is a sharp change in the rate of cell increase from the old rate to the new rate. This occurs 60 min after the shift-up (Fig. 1). Because there is a lag in the change in the rate of cell division, while cytoplasm synthesis increases to the new rate almost immediately, during the shift-up period there is an increase in cell size producing the larger-sized cells in the faster growth medium.

1.4 Classical Growth Pattern Is Merely a Series of Shift-ups and Shift-downs

The classical growth pattern for a culture can now be seen as a series of shift-ups and shift-downs. When an overgrown culture (nongrowing, and thus of essentially zero growth rate) containing small cells is diluted into fresh medium, there is a "shift-up" in growth rate. The mass increases immediately with no cell division occurring. The "lag" phase is thus one of a lag in cell number increase, but there is essentially no lag when considering mass increase. After the normal cell size is achieved for that medium, both the mass and the cell number increase in parallel. The rate of cell increase is determined by the medium supporting the more rapid growth. There is a constant larger-size cell during exponential growth. The reverse occurs as growth begins to slow down and the cells approach the stationary phase. The rate of mass synthesis decreases first, followed later by a cessation in the increase in cell number. Because division continues after mass increase ceases, the average cell size decreases in an overgrown culture.

2 The Bacterial Division Cycle

2.1 Cell Age and the Age Distribution during Balanced Growth

By convention, a newborn cell has an age of 0.0 and grows during the division cycle to divide at age 1.0. The cell ages during the division cycle are thus numbers between 0.0 and 1.0 indicating where, in the division cycle, a cell is located at a particular instant. A cell half-way between birth and division is age 0.5. Cell age, by definition, increases linearly during the division cycle. However, cells at the same absolute time after birth are only approximately the same cell-cycle age because of the variability in the absolute time required for the division cycle of an individual cell.

In a growing culture, the distribution of cell ages is not uniform. There are twice as many newborn cells as dividing cells. The age distribution is given by the formula $N = 2^{1-x}$, where x is the cell age between 0.0 and 1.0. This formula indicates that there are twice as many newborn cells ($x = 0.0$) as dividing cells ($x = 1.0$). If all cells grew with exactly the same interdivision time, this formula would give the age distribution exactly. However, because of cycle variability there is a smoothing of the function and the actual distribution is an approximation of the theoretical distribution. Because of the age distribution, the properties of an exponentially growing culture are independent of time. This means that all patterns of synthesis within the division cycle give an exponentially increasing amount of material in a growing culture. This is because the age distribution is constant during steady state, exponential growth. Thus, whether something is

made linearly, exponentially, or at an instant during the division cycle, in an exponentially growing culture the amounts of all cell components increase exponentially and in parallel. This is referred to as balanced growth. The observed balanced growth is the result of the age distribution during growth being invariant.

Given that between the birth of a cell and its subsequent division, all of the cell components double, we can ask, ''At what rate is material synthesized during the division cycle of an individual cell, and how does the cell ensure that there is a precise doubling of cell components by the time the cell divides?'' Let us first analyze which components must be dealt with in terms of the division cycle.

2.2 Aggregation Theory and the Control of Synthesis during the Division Cycle

In economics, the aggregation problem is how to combine various sectors of an economy. Should the figures for the production of capital machinery be combined with those for the production of consumer goods? Is paper produced for boxes in the same economic category as stationery? It is difficult to treat each item in an economy individually; some aggregation is necessary in order to understand the whole system.

Now, consider the aggregation problem for the analysis of the bacterial division cycle. How should one aggregate the different cell components in order to achieve an understanding of the biochemistry of growth and division? Is there a unique pattern of synthesis during the division cycle for each enzyme, or are there a limited number of patterns with different enzymes or molecules synthesized according to any one of these patterns? Are there ways of grouping proteins or RNA molecules so that one can consider classes of molecules rather than individual molecular species? Should we consider the cell membrane as a different category from that of peptidoglycan? There are approximately a thousand proteins in the growing cell, and if each protein had a unique cell-cycle synthetic pattern, or if there were only a few enzymes exhibiting any particular pattern, we would have an insuperable task describing the biosynthesis of the cell during the division cycle.

Fortunately, one need consider only three categories of molecules, each of which is synthesized with a unique pattern. The growth pattern of the cell is the sum of these three biosynthetic patterns. The first category is the cytoplasm, which is the entire accumulation of proteins, RNA molecules, ribosomes, small molecules, water, and ions that make up the bulk of the bacterial cell. It is the material enclosed within the cell surface that is not the genome. The second category is the genome, the one-dimensional linear DNA structure. The third category is the cell surface, which encloses the cytoplasm and the genome. The surface is composed of peptidoglycan, membranes, and membrane-associated proteins and polysaccharides. Everything in the cell fits into one of the three categories, and each category has a different pattern of synthesis during the division cycle. These three patterns are simple to understand as they can be derived from our current knowledge of the principles involved in the biosynthesis of the cytoplasm, the genome, and the cell surface.

The division cycle of bacteria in general may be best described by discussing the division cycle of the bacterium about which most is known, *E. coli*, and then describing

other bacteria and their patterns of growth and division with respect to this archetypal pattern. The division cycle of *E. coli* will be described, indicating how the various components of the cell are made and distributed into two new daughter cells.

3
Synthesis of Cell Components during the Division Cycle

3.1
Cytoplasm Synthesis during the Division Cycle

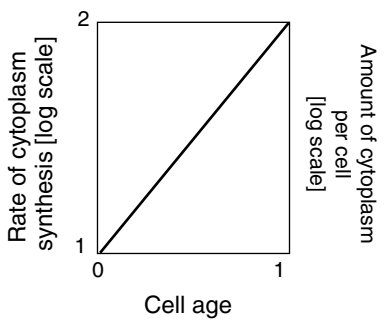
3.1.1 Exponential Cytoplasm Synthesis during the Division Cycle

Consider a unit volume of cytoplasm. It contains enzymes required for the breakdown of nutrients, enzymes for the production of energy for biosynthesis, enzymes for the biosynthesis of low molecular weight precursors of macromolecules, and enzymes for the synthesis of macromolecules. Each unit of cytoplasm produces a small amount of new cytoplasm over a small interval of time. If the new cytoplasm is indistinguishable from the old, and if the new cytoplasm acts to synthesize more cytoplasm immediately, then the pattern of cytoplasm synthesis is exponential. This is because after each interval of synthesis, the rate of synthesis increases owing to the new increment of material added to the cytoplasm. This exponential pattern is illustrated in Fig. 2 with both the rate of synthesis and the amount of material increasing exponentially during the division cycle.

Fig. 2 Cytoplasm synthesis during the division cycle. Both the rate of cytoplasm synthesis and the pattern of accumulation of cytoplasm are exponential during the division cycle.

The pattern for cytoplasm as a whole is reflected in the synthesis of the individual cytoplasmic components. There are no changes in the specific rate of synthesis or pattern of cytoplasm synthesis that are related to any particular cell-cycle event. (Actually, there is a minor *caveat* to this generalization, which is treated below.) No particular molecule of the cytoplasm is made differently from any other molecule of the cytoplasm during the division cycle. In addition, there is no variation, during the division cycle, in the relative concentration of any component of the cytoplasm. All parts of the cytoplasm accumulate exponentially during the division cycle, and this pattern is unchanged even when the cell is dividing. At the instant of division, the combined rate of cytoplasm synthesis in the two new daughter cells is precisely equal to the synthetic rate in the dividing mother cell.

One minor exception to the rule that specific proteins are made exponentially during the division cycle regards the effect of momentary sequestration of DNA upon replication. Specific regions of DNA are sequestered in the membrane at different times during the cell cycle at the time of their replication. During this sequestration period, the DNA is not available for transcription. Thus, for all genes there



is a time during the division cycle at which gene expression is prohibited. This momentary cessation of transcription should not obscure the more fundamental point that there does not appear to be any specific control of gene expression for any gene during the division cycle that is related to the regulation of that gene during the division cycle. One should imagine this cessation of gene expression as merely a necessary accommodation of transcription to the needs of the cell for DNA replication. It could be imagined that if the cell were able to replicate DNA without any cessation of transcription, there would be no reason to expect that the cell would alter specific gene expression at any point during the division cycle.

The evidence for a smooth, continuous, and exponential increase in cytoplasm comes from experiments that use the membrane-elution method, colloquially referred to as the *baby machine* (see below). The pattern of DNA synthesis during the division cycle, which was subsequently shown to be correct by flow-cytometric and other analyses, was actually discovered using the membrane-elution method. Thus, the results from a method capable of producing an accurate analysis of biosynthesis during the division cycle have confirmed the exponential synthesis of cytoplasm.

In addition to this experimental support, an evolutionary argument can be made for an invariant rate of accumulation of cytoplasm during the division cycle. If the synthetic rate of an enzyme changed abruptly during the division cycle, there would be a relative excess or deficiency of that enzyme at some point during the division cycle; this would be an inefficient use of resources. The optimal allocation of resources is for each component to be at a constant concentration during the division cycle. Cells would not evolve controls that make them less efficient in cell production. The ideal pattern of cytoplasm synthesis is an invariant cytoplasm composition during the division cycle.

A third argument supporting exponential cytoplasm synthesis is that only this pattern is explained in known biochemical terms. The cycle-independent exponential synthesis of cytoplasm can be derived from our current understanding of the biochemistry of macromolecule synthesis. Enzymes make RNA and protein, which make ribosomes, which then lead to more protein synthesis. More proteins mean more RNA polymerases, more catabolic and anabolic enzymes, and the continuously increasing ability of the cell to make more and more cytoplasm. In contrast, if newly synthesized material were *not* active or available for synthesis when made, but instead was recruited for biosynthesis only at the instant of division or at some specific cell-cycle age, one would have linear cytoplasm synthesis during the division cycle. There are no known mechanisms enabling the cell to distinguish between newly synthesized cytoplasm and old cytoplasm, or which lead to cell-cycle-specific variation in the synthetic rate of any particular molecule during the division cycle. We therefore conclude that in theory as well as in practice, cytoplasm increases uneventfully and exponentially during the division cycle.

3.1.2 Variation in the Rate of Cytoplasm Increase

The continuous variation in allowable growth rates may be understood by partitioning the cytoplasm into those molecules involved in cytoplasm synthesis and that are absolutely necessary for growth (ribosomes, RNA polymerases, etc.) and those molecules that are involved in dispensable

syntheses (e.g. enzymes involved in amino acid biosynthesis). In a minimal medium, in which many dispensable enzymes are being synthesized, the ribosomes may be considered to be involved in the synthesis of ribosomal protein and a large number of dispensable proteins. Since only a fraction of the ribosomes are making ribosomal protein at any moment, the time for a doubling in the ribosomal content is relatively long. As one increases the number of nutrients in the medium, thus relieving the cell of having to make the dispensable enzymes, a larger fraction of ribosomes are involved in ribosomal protein synthesis. Thus, in rich medium the time for ribosome number to double is shorter than in poor medium. The variation in growth rates is thus a reflection of the continuous ability of the cell to partition the ribosomes (or the RNA polymerases) between making ribosomal components or nonribosomal components.

Considering the time required for a ribosome to make another ribosome (i.e. using 15 amino acids incorporated in a protein chain in a second), one can calculate that it would take eight minutes for one ribosome to synthesize a single ribosome. If a cell were in some way supplied with all proteins other than ribosomes, one could consider that the fastest rate of cell doubling would be eight minutes, the time for ribosomes to double their number.

3.2 DNA Synthesis during the Division Cycle

One of the most important generalizations regarding the regulation of linear macromolecule synthesis is that the rate of synthesis is regulated at the point of initiation of polymerization. This principle is exhibited most clearly in DNA replication, where the process of initiation of replication can be clearly dissociated from the continued replication of DNA that has already initiated replication. If one inhibits the initiation of replication, then the rounds of DNA replication in progress will continue until their normal termination.

3.2.1 Pattern of DNA Synthesis during the Division Cycle

The DNA synthesis pattern during the bacterial division cycle (specifically for *E. coli* and related bacteria) is composed of one or more periods of constant rates of DNA accumulation (Fig. 3). In cells with a 60 min interdivision time, there is a constant rate of DNA synthesis for the first 40 min, with one bidirectional pair of replication forks, followed by a zero rate of synthesis during the last 20 min. In cells with a 30 min interdivision time, there is a constant rate of DNA synthesis for the first 10 min, which falls to a constant rate that is two-thirds of the initial rate for the last 20 min. In cells with a 20 min interdivision time, there is a constant rate of DNA synthesis throughout the division cycle. Other growth rates have similar particular patterns of DNA synthesis.

The constant rates of DNA synthesis can be understood in terms of the molecular aspects of DNA synthesis. DNA is synthesized by the movement of a replication point along the parental double helix, leaving two double helices in its wake. The rate of movement of a growing point appears to be invariant and independent of its location in the genome. This means that the rate of DNA synthesis is proportional to the extant number of replication points. The number of replication points is constant for any period of the division cycle. Thus, the rate of DNA synthesis during any period of the division cycle is also constant. The

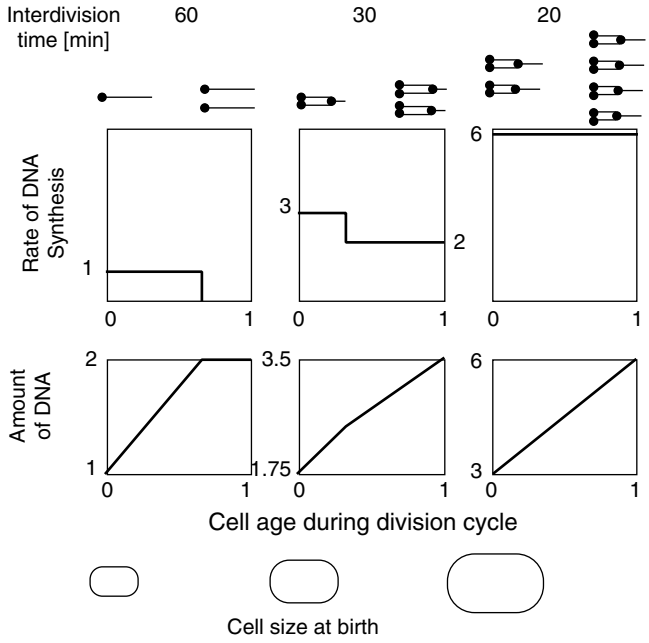


Fig. 3 DNA synthesis during the division cycle. Three different patterns are illustrated for cells growing with 20, 30, and 60 min doubling times. For each growth rate, the time from initiation to termination of DNA replication is 40 min. The time between termination of replication and cell division is 20 min. The proposed chromosome patterns at the start and finish of the division cycle are illustrated above the graphs. In addition to the rate of DNA synthesis during the division cycle, the pattern of accumulation of DNA during the division cycle is presented. Accumulation of DNA is composed of periods of linear synthesis. The rates during these periods are proportional to the existing number of growing points. The graph of the rate of synthesis is the differential of the accumulation plot. A representation of the cell size expected for cells at the start of the division cycle is presented below each synthetic pattern. The size of the newborn cells is in the ratio of 1 : 2 : 4 in the three cultures illustrated here. The number of new initiations at the start of each division cycle is also in the ratio of 1 : 2 : 4.

pattern of constant rates of synthesis is derived from, and is consistent with, our understanding of the biochemistry of DNA synthesis.

Embedded in the patterns of Fig. 3 are the two major rules for the determination of the pattern of replication of DNA during the bacterial division cycle. The first rule is that once DNA replication is initiated at the origin of replication, the time for a complete round of replication – the C-period – is relatively invariant (40 min in *E. coli* at 37 °C). The second rule is that the time between termination of replication and cell division – the D-period – is also relatively invariant.

The constant C- and D-periods are most clearly evident in the 60 min cells in Fig. 3.

At other growth rates, the patterns of synthesis appear more complicated, but this is due to the possibility of initiation occurring before completion of previous rounds of replication and the possibility of initiation of replication occurring in one division cycle and replication of the chromosome being completed in a subsequent division cycle.

3.2.2 Regulation of Initiation of DNA Replication

Why is replication initiated at these particular times during the division cycle? How is the initiation process regulated? Rounds of replication are initiated in a bacterial cell when the amount of cell mass or something proportional to the cell mass (the "initiator") is present at a certain amount per origin. Initiation of new rounds of replication occurs once per division cycle when the mass (or "initiator") per origin reaches a fixed value. In the 60 min cell, initiation occurs at one origin with a cell of unit size (size 1.0). In the 30 min cells, there are two origins in the newborn cell and the size of the newborn cell is twice that of a 60 min cell. And the 20 min cell has four origins initiated in the newborn cell and the cell size is four times the newborn 60 min cell. Thus, not only does the DNA per cell increase with growth rate but the average cell size increases with growth rate as well. In the cells shown in Fig. 3, the relative sizes of the newborn cells, as well as the average cell in the culture, are in the ratio of 1 : 2 : 4. This increase in cell size with growth rate is consistent with the exponential increase in cell size as a function of the inverse of the doubling time.

The actual nature of the initiator is not known, but a number of candidate molecules have been identified. Among these, the DnaA protein appears as a good candidate for the regulator of DNA initiation.

Alternative models of initiation have been proposed, such as the sudden accumulation of an inhibitor of initiation that is diluted out by cell growth. This model does not accommodate the constant synthesis of cell-cytoplasmic components. In all cases, it is indistinguishable from the initiator accumulation model, and there is no evidence for such an inhibitor being synthesized during the division cycle.

3.2.3 The Specific Origin of Replication

A specific sequence of DNA in the bacterial genome is the origin of replication (oriC). The required sequence (for *E. coli*) is 245 bp. Within this sequence are 5 highly conserved sequence blocks of 15 to 20 bp. These conserved regions are interspersed with sequences that are random. Regions of random sequence but of fixed length separate the conserved regions. Thus, the length of separation of conserved sequences is more important than the specific sequence between the conserved sequences. Four sequences of 9 bp are specific recognition sites for the binding of dnaA, the specific initiator protein. In addition, there are three 13 bp regions that are sites for opening the duplex DNA for initiation. Finally, there are 14 GATC sequences located in the origin (oriC) region and the neighboring regions. These 14 four bp sequences are expected to occur at a much lower frequency if they were not a necessary part of the *E. coli* origin.

The ultimate proof that this sequence is the origin of replication is the production of minichromosomes, small replicating circles of DNA that have the bacterial origin of replication. An *E. coli* cell can have many copies of the minichromosome

without any apparent impairment of cell growth.

3.2.4 Protein Factors Controlling DNA Replication

Initiation of replication of DNA is a function of numerous proteins. The key regulatory protein appears to be the product of the *dnaA* gene. The dnaA protein binds to the 9 bp ''dnaA boxes'' in the oriC region. After binding to the origin, the protein promotes melting of the DNA (i.e. separation of the DNA strands in a local region) and helps in loading additional proteins such as the dnaB protein. After this initial opening of the DNA strands, replication fork movement is allowed to proceed bidirectionally from the origin.

Initiation of replication is distinct from the continued replication of DNA that has been initiated. Once initiated, DNA replication can continue even though the accumulation of cell cytoplasm is inhibited.

3.2.5 Chromosome Organization and Bidirectional Replication

The phenomenon of bidirectional replication has two effects on the organization of the chromosome. One effect is the variation in the relative abundance of G residues versus C residues in one of the strands. While G = C in the double helix, such an equality need not exist in a given strand or in a particular region of a strand. As a general rule, it is found that in the two halves of the bidirectionally replicated bacterial genome, one half of the chromosome (e.g. that from noon past three down to six on a clock representation of the genome) has G > C and the other half (noon, past nine, down to six) has G < C. If one calculates the G − C/G + C for a running window of nucleotides, and accumulates the value of this ''GC-skew,'' there is a valley that corresponds to the origin and a peak that corresponds to the terminus. As long as one reads the strand in the 5′ to 3′ direction, the location of the peak and the valley is independent of the strand being used to define the origin and the terminus.

The bidirectional organization of the genome also affects the direction of gene transcription. As a general rule (with numerous exceptions), the direction of gene transcription is in the same direction as the movement of the replication fork. The rationale for this phenomenon is that this correspondence of direction of replication and transcription reduces the ''head-on collision'' of replication and transcription. The fact that there are many exceptions means that the replication system can accommodate running into transcriptional units without a problem.

3.2.6 DnaA Protein Is Involved in Initiation of DNA Replication

The DnaA protein, identified by mutants affecting the initiation of DNA replication and not the progression of rounds of replication already in process, appears to be the ultimate regulatory protein with regard to the initiation of DNA synthesis. The initiation process involves the cooperative binding of approximately 20 DnaA protein molecules to the origin of replication. This complex then leads to the open complex in which a region of AT-rich 13-mer repeats denatures so that single-stranded DNA is exposed. Other proteins such as the DnaB helicase are now introduced into the forks of the melted DNA where it expands the region of single-stranded DNA. Other molecules then join the initiation complex with the final loading of DNA polymerase III. When this occurs, the replication of DNA progresses

around the genome to the opposite end of the genome where replication terminates.

3.3 Surface Synthesis during the Division Cycle

3.3.1 Peptidoglycan Synthesis during the Division Cycle

The cell surface is made to perfectly enclose, without excess or deficit, the cytoplasm synthesized by the cell. Cell cytoplasm increases continuously during the division cycle (described above), and therefore the cell surface is made continuously. How is the bacterial cell surface made and duplicated during the division cycle? What is the rate and topography of cell-surface synthesis during the division cycle?

Consider an imaginary cell in which the cytoplasm is enclosed in a cell-surface tube that is open at each end; the cytoplasm remains within the bounds of the tube. The cytoplasm in the newborn cell is thus encased in the cylinder of cell surface that is made up of membrane and peptidoglycan. As the cytoplasm increases exponentially (see above), the tube length increases to exactly enclose the newly synthesized cytoplasm. In this imaginary case, the cell surface increases exponentially in the same manner as the cytoplasm. When the cell cytoplasm doubles, the tube divides into two new cells and the cycle repeats. In this imaginary cell, the cytoplasm increases exponentially, the internal volume of the cell increases exponentially, the surface area increases exponentially, and the density of the cell, that is, the total weight of the cell per cell volume, is constant during the division cycle.

However, a real rod-shaped cell does have ends, and therefore the pattern of cell-surface synthesis during the division cycle is not simply exponential. If the cell surface were synthesized exponentially, the cell volume cannot increase exponentially. Since the cytoplasm increases exponentially, there would have to be a change in cell density. (In theory, it may be that major changes in cell shape could allow a pure exponential increase in cell mass and cell surface, but such changes are clearly not observed during the cell-division cycle.) Cell density, however, is constant during the division cycle. A proposal for cell-surface synthesis that allows an exponential increase in cell volume, and therefore a constant cell density, is presented in Fig. 4. Before invagination, the cell grows only in the cylindrical sidewall. After invagination, the cell grows in the pole area and the sidewall. Any volume required by the increase in cell cytoplasm that is not accommodated by pole growth is accommodated by an increase in sidewall. The cell is considered a pressure vessel, and when the pressure in the cell increases, there is a corresponding increase in cell surface area. The pole is preferentially synthesized and any residual pressure due to new cell cytoplasm that is not accommodated by pole growth is relieved by an increase in cylindrical sidewall area.

The resulting pattern of synthesis is approximately exponential. The formula describing surface synthesis during the division cycle is a complex one, including terms for the shape of the newborn cell, the cell age at which invagination starts, the pattern of pole synthesis, and the age of the cell. One consequence of this model of surface synthesis is that at no time is surface synthesis exponential, since the rate of surface synthesis is not proportional to the amount of surface present over any period of time.

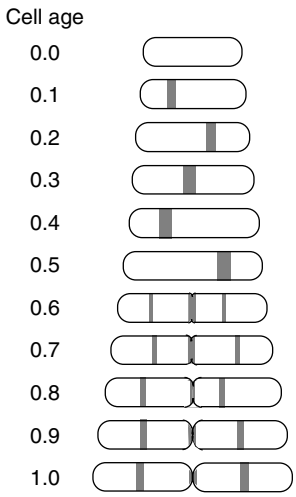

Fig. 4 Cell-surface synthesis during the division cycle. Before invagination, the cell grows only by cylinder extension. Each cell is drawn to scale, with the volume of the cells increasing exponentially during the division cycle. The shaded regions of the cell indicate the amount and location of wall growth (whether in pole or sidewall) each tenth of a division cycle. The width of the shaded area is drawn to scale. Cell-surface growth actually occurs throughout the sidewall and not in a narrow contiguous zone. The variable locations of wall growth in this figure have no specific meaning, but are meant to show synthesis occurring all over the sidewall during the division cycle. Before invagination, the ratio of the surface increase to volume increase is constant. When pole synthesis starts, at age 0.5 in this example, there is an increase in the ratio of the surface increase to the volume increase. Any volume not accommodated by pole growth is accommodated by cylinder growth. At the start of pole growth, there is a reduction in the rate of surface growth in the cylinder. As the pole continues to grow, there is a decrease in the volume accommodated by the pole and an increase in the rate of growth in the sidewall.

As with cytoplasm and DNA synthesis, we can derive the cell-cycle pattern of surface synthesis from our understanding of the molecular aspects of peptidoglycan synthesis. The peptidoglycan sacculus of the cell is composed of glycan strands encompassing the cell, perpendicular to the long axis, as shown in Fig. 5. These strands are cross-linked by peptide chains. Because the cross-linking in the load-bearing layer is not complete, one can have new strands in place, below the taut load-bearing layer, prior to the cutting of the bonds linking old strands. As shown in Fig. 5, the load-bearing layer is stretched by the turgor pressure in the cell. An infinitesimal increase in cytoplasm leads to an infinitesimal increase in the turgor pressure of the cell. This increase in turgor pressure places a stress on all of the peptidoglycan bonds, thus reducing the energy of activation for bond hydrolysis. The result is that there is an increase in the cutting of stressed bonds between the glycan chains. When a series of cuts is made, allowing the insertion of a single new strand into the load-bearing layer, there is an infinitesimal increase in cell volume. This increase in volume leads to a reduction of the stress on the remaining bonds. By a continuous repetitive series of cytoplasm increases, surface stresses,

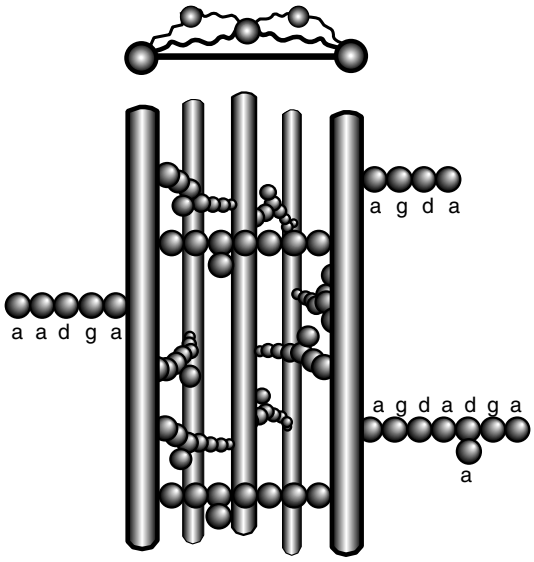

Fig. 5 Three-dimensional representation of peptidoglycan structure. This is an idealized representation of peptidoglycan structure as seen from the outer surface. The thick bars represent glycan chains at the outside of the peptidoglycan layer. The thinner bars represent glycan chains below the outer layer. The stretched chains of circles represent amino acids cross-linking the glycan chains. The chains below the stretched surface of the cell rise to the outer layer when the taut layers of the peptidoglycan are hydrolyzed. The figure shows a cross-sectional view through the glycan chains illustrating the taut outer layer and the more loosely inserted inner material. The letters indicate the amino acids composing the cross-links; a = alanine, d = diaminopimelic acid, and g = glutamic acid, with italicized letters present in the D-configuration.

enzymatic cuts, and volume increases, one gets an increased cell volume that precisely accommodates the increase in cell cytoplasm.

An inside-to-outside mode of peptidoglycan growth, similar to that for *Bacillus subtilis*, has been proposed for *E. coli*. This proposal is based on the observed recycling of murein, the calculated amount of peptidoglycan per cell, and the existence of trimeric and tetrameric fragments that are consistent with a multilayered peptidoglycan structure. The insertion of new peptidoglycan strands in an unstressed configuration prior to their movement into the load-bearing layer of the peptidoglycan can explain all of these observations. The recycling of peptidoglycan may be a strain-specific result, as there is no major release or recycling of peptidoglycan in *Salmonella typhimurium* or in *E. coli* B/r. At this time, the inside-to-outside mode of surface growth cannot be excluded.

Although this discussion of the rate of surface synthesis during the division cycle has dealt primarily with peptidoglycan, it applies equally to membranes and other surface-associated elements. The cell membrane grows in response to the increase in peptidoglycan surface and coats the peptidoglycan without stretching or buckling. The area of the membrane increases in the same way in which bacterial peptidoglycan increases.

One must make distinctions among cell components with regard to their location in the cell, rather than with regard to their chemical properties. Cell proteins can be divided into two categories – those associated with the cytoplasm and those associated with the surface. Proteins associated with the membranes are included in the surface category of synthesis during the division cycle. If a bacterial cell had a histone-like protein associated with DNA, there would be a third category of protein-synthetic patterns, proteins synthesized

during the division cycle with constant rates of synthesis. Proteins are synthesized during the division cycle with a pattern that is presumably consistent with their final location or category. Proteins are not a monolithic group nor are they divided into a large number of groups. The three-category system proposed here allows us to conceptualize the possible patterns of protein synthesis observed during the division cycle.

3.3.2 The Invagination Process

The division of the bacterial cell into two daughter cells occurs by the formation of two new poles in the middle of the dividing cell. As there are very few DNA-less cells produced during balanced growth, the division process must be coordinated with the replication process so that division does not occur until two genomes are present. The invagination process that forms two poles in the middle of the cell involves a complex process whereby there is an inward growth of the peptidoglycan and the associated membrane of the cell surface.

One of the earliest events related to the invagination process is the localization of the FtsZ protein to the future site of pole formation. The FtsZ protein is localized to the division site in a pattern called the *FtsZ ring*. The FtsZ protein accumulates at the mid-cell site where division will occur before any visible invagination. During the invagination process, the FtsZ protein is located at the leading edge of the invagination process. Thus, the FtsZ ring continues to define a ring of decreasing size as invagination proceeds.

Other proteins necessary for invagination and division are apparently localized at the center of the cell because of their association with FtsZ.

3.3.3 FtsZ Protein Is Involved in Septum Formation and Cell Division

Recent results indicate that the tubulin-like FtsZ protein plays a central role in cytokinesis or cell division as a major component of a contractile cytoskeleton. An indication that the FtsZ protein is the key initiator of septation is that mutants of this protein that form filaments show no indication of any constriction. Other septation mutants presumed to be later in the pathway of septum formation do show some indication of septation. The FtsZ protein resembles the eukaryotic tubulin molecule and this similarity has led to speculations that the FtsZ protein has cytoskeletal properties that allow it to form the new pole in the middle of the cell.

3.3.4 Localization of the Division Site

The actual mechanism by which the division site is localized at mid-cell position is unknown. One model of the division-site localization proposes that the site exists prior to any observation of FtsZ localization. An alternative model proposes that the division site is determined in some way by the reaction of the cell surface to the presence of DNA; the absence of DNA in the center of the cell would thus lead to invagination-site localization.

An understanding of site location is strongly influenced by the existence of minicells. If invagination occurs, upon occasion, near a pole rather than in the center of a cell, a very small DNA-less "minicell" is produced that is essentially two poles without an intervening sidewall. The genetics of minicell formation is complicated, but the main idea is that the products of the min genes have a negative function and normally inhibit abnormal invagination sites. Thus, inactivation of any of a number of min genes leads to minicell

formation owing to the inappropriate location of invagination sites.

4 Plasmid Replication during the Division Cycle

4.1 High-copy Plasmids

If a cell has a large number (20–100) of plasmids per newborn cell, then one can consider that these plasmids replicate during the division cycle in proportion to those present (i.e. exponentially) and then assort themselves randomly into the newborn cells. Because the plasmid number is high, there is little chance of one of the daughter cells ending up with no plasmids and with all of the plasmids segregating to the other daughter cell. This pattern appears to be the case for naturally occurring, high-copy number plasmids.

One possible exception is the artificial plasmid made by cloning the origin (oricC) region of the bacterial chromosome. This appears to have a random assortment mechanism, but it is synthesized at a precise time during the division cycle that coincides with the normal time at which the chromosome initiates replication.

4.2 Low-copy plasmids

Low-copy plasmids are usually larger than high-copy plasmids and are present on the order of 1 to 2 per cell. Examples of such plasmids are the F-factor and the P1 plasmid. These replicate in a precise way at a particular time during the division cycle. The rules of their replication are similar to that regulating chromosome replication, with initiation of plasmid replication occurring when a fixed amount of cell mass is present per plasmid origin.

4.3 Minichromosome Replication during the Division Cycle

Minichromosomes replicate at the same time as normal chromosome initiation. The behavior of minichromosomes is paradoxical in that in a cell with numerous additional origins of replication there would be a competition for the ''initiator'' of replication. Such a competition would lead to abnormal cell sizes or some alteration in cell growth pattern. No such alteration is observed.

5 Segregation of Cell Components at Division

Producing the right amount of material so that the cell can divide is not enough for a successful division cycle. At division, the material in the mother cell must also be properly apportioned to the newborn cells. In a cell that divides to produce two equivalent daughter cells, the segregation problem is to ensure that both cells have the same amount of each portion of the cell material. Let us see how the three categories of material in the mother cell are segregated properly to the new daughter cells.

5.1 Segregation of Cytoplasm

The cytoplasmic components of the cell appear to segregate randomly at division. There does not appear to be any compartmentalization or hindrance to segregation of cytoplasm (Fig. 6).

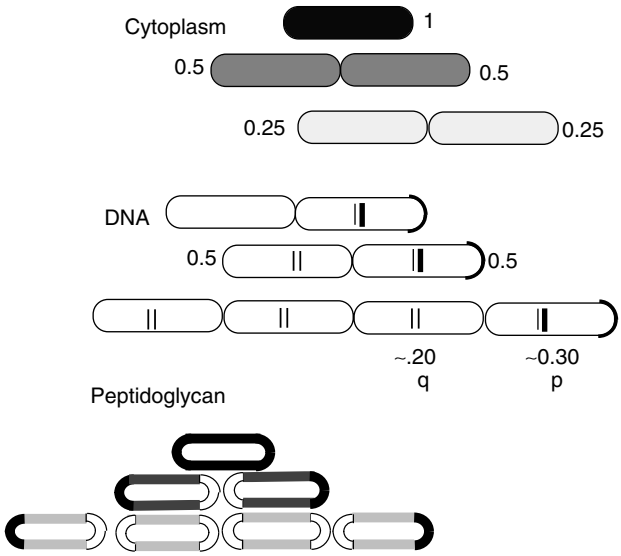

Fig. 6 Segregation of cytoplasm, surface, and DNA at division. The cytoplasm of the cell is segregated randomly at division. Each daughter cell shares equally in the parental cytoplasm (ribosomes, soluble proteins, ions, etc.), which can be considered randomly distributed throughout the dividing cell. The DNA is segregated nonrandomly, but each daughter cell gets a complete and equal complement of DNA from the dividing cell. The nonrandom segregation is at the level of a single strand. Since each DNA duplex is made up of an ''older'' strand and a new complement made on the older strand, and each cell is composed of an ''older'' pole and a pole just made at the previous division, one can see whether strands of one age go preferentially toward one or the other age pole. Experimental analysis indicates that the DNA strands segregate as though the older DNA strand goes preferentially toward the pole that it went to at the previous division. This may be phrased as the newer strand goes toward the newer pole. The degree of nonrandom segregation is not perfect, but is stochastic, and is approximately 60/40 rather than 50/50. The surface of the cell segregates to the daughter cells at division such that the poles are conserved and the sidewall segregates with no apparent conservation of sidewall peptidoglycan. It is not clear whether insertion of new wall material over the side is perfectly uniform or whether there is some nonuniform pattern of insertion.

5.2 Segregation of DNA

DNA segregates so that each daughter cell receives a complete genome from the dividing mother cell (Fig. 6). As the DNA nucleoid is relatively compact within a dividing cell, if the nucleoids were apportioned completely randomly, one might expect that at some divisions one of the daughter cells would not receive any DNA and the other daughter cell would

receive two genomes. That this is a rare event supports the notion that segregation of the DNA is a regulated and deterministic process that leads to very few nonnucleated cells in a culture.

In addition to the segregation of individual nucleoids, the separate strands of the DNA have rules that describe their segregation and which are compatible with the deterministic equipartition of DNA to the two daughter cells. As all rod-shaped cells are asymmetric in that one of the poles is the new pole (produced at the last division) and one pole is necessarily older, one can see how older DNA strands and newer DNA strands (the newer strands having just been made on an older, preexisting strand) segregate with regard to pole age. The general rule is that the older strands segregate slightly preferentially to the older poles and the younger strands segregate preferentially to the newer or younger poles. This phenomenon is consistent with other data that indicate some attachment of the DNA to the cell surface.

5.3
Segregation of the Cell Wall

The peptidoglycan is a large macromolecule that grows by intercalation of new material between old material. Since all the peptidoglycan is covalently linked in one macromolecule, there is no ability for the peptidoglycan components to move with respect to each other. The segregation of cell wall material is therefore determined by the location of the cell wall material. Once in place, the wall segregates into the newborn cells so that the old poles go to each cell, and the sidewall is segregated to the newborn cells (Fig. 6).

6
Are There Events during the Division Cycle?

There are only four discrete events that occur during the division cycle of a growing rod-shaped bacterial cell. They are (1) the initiation of DNA replication, (2) the termination of DNA replication, (3) the initiation of pole formation, and (4) the completion of pole formation. Other aspects of cell growth are too continuous to be considered cell-cycle-specific events. For example, the addition of new nucleotides at position 43,567 on the chain of DNA may be considered a unique event, and one that occurs at a particular time in the division cycle, but because of cell-cycle variability, the time of this synthetic occurrence can never be precisely obtained. The time of insertion of a particular nucleotide pair has no meaning for the cell cycle; only the initiation and termination of DNA replication are important. With regard to the division cycle, the DNA is an amorphous material with no biochemical specificity along the strand.

Similar considerations apply to the cell surface and the cytoplasm. No aspect of peptidoglycan strand insertion is unique in time during the division cycle. A new strand is inserted at random sites in response to the stretching of the cell surface. This may occur in one cell at position 0.376 of the cell length; at the same time, in another cell, the new strand may be inserted at position 0.549. For an analysis of the cell cycle, we should consider pole and sidewall growth as uneventful extensions of the cell surface. Regarding the cytoplasm, one may consider the increase in ribosome content from 37,411 to 37,412 an event; but such an individual event is not measurable and is without meaning in the cell cycle. Thus, cytoplasm synthesis,

DNA synthesis, and cell-surface synthesis are uneventful during the division cycle.

In contrast to our understanding of the principles of cytoplasm, cell-surface, and DNA synthesis, the biochemical mechanisms of the four events occurring during the division cycle – the initiation and termination of DNA synthesis and the initiation and cessation of pole formation – are still unknown. While a great deal is known about the biochemistry of initiation of DNA replication, the mechanism by which this initiation is regulated is less well understood. In addition, very little is known of the biochemical principles involved in either the termination of DNA replication or the start and cessation of pole formation. A cell-surface structure, the periseptal annulus, has been proposed as a possible first step in the formation of a new pole. If the periseptal annulus is the start of pole formation, the important question is whether there are definable steps between the formation of the periseptal annulus and the start of invagination.

7
Do Checkpoints Control the Bacterial Cell Cycle?

In eukaryotic cell-cycle studies, the concept of ''checkpoints'' looms large. Checkpoints are the postulated functions of a cell that determine that one function is properly completed before a subsequent function occurs. Thus, in eukaryotic cells it is postulated that a checkpoint function determines that DNA has replicated completely and properly before allowing mitosis to occur. The checkpoint is thus a valuable function that prevents abnormal functions from occurring.

Studies of this type of phenomenon in bacteria can provide a corrective lens for understanding or more rigorously defining checkpoints. In bacteria, if DNA synthesis is inhibited, cells with only one genome (i.e. cells that have not completed replication of a total chromosome) do not divide. Even when DNA is inhibited or damaged, a cell with two genomes will divide, while a cell with one genome will not. Thus, in bacteria, DNA damage *per se* does not activate a checkpoint to prevent division. It is believed that the presence of a single genome in the center of a cell prevents division by its central presence, not the activation of a function that checks for completion of DNA replication.

The bacterial experience thus suggests that a distinction should be made between the existence of a function external to the tested function (i.e. some activity that checks on whether DNA replication has been completed) and the actual function itself acting as a brake on further activity. The failure to complete DNA replication is the inhibitor of division, and there is no checking by some ''checkpoint'' activity.

A similar analysis may be applied to the ubiquitous postulation of restriction points in eukaryotic cells. Restriction points are points or events postulated to exist in the G1-phase of the division cycle. Passage of a cell through the restriction point is a requirement for entering the S-phase and eventual division. The restriction point was defined by the effect of different starvation regimens on DNA replication and the resumption of DNA replication following release from starvation.

It is interesting that a bacterial restriction point was postulated to exist before the proposal of the eukaryotic restriction point, although the term *restriction point* was not used. Subsequent analysis of the bacterial restriction point indicated that the proposed control point was an experimental artifact related to leakage of

synthesis under starvation conditions. The eukaryotic restriction point is subject to the same critique.

8 Temporal Variation of the Bacterial Division Cycle

Division cycles in a culture are not precisely timed. There is a great deal of variability in division cycles, with a culture having a 60-min doubling time probably having cells with interdivision times between 40 and 100 min. The variability of the division cycle can be visualized as due to the variability of the separate components that make up the division cycle. Thus, for two identical newborn cells one can have the subsequent division occurring at different times because of (1) variability in mass synthesis in the two cells leading to variation in the time of initiation of DNA replication, (2) variation in the rate of DNA replication in the two cells, (3) variation in the time between termination and division, (4) and variation in the equality of division (which leads to variation in the next division cycle).

9 Alternative Bacterial Division Cycles

9.1 *Caulobacter crescentus* Division Cycle

At first glance, the division cycle of the stalked bacterium *Caulobacter crescentus* appears quite different from that of *E. coli*. At division, two different-sized and different looking cells are produced (division is not in the middle of the mother cell and one cell is stalked and the other is flagellated), the DNA patterns during the division cycle differ in each of the daughter cells, and there are cell-cycle-specific syntheses of flagellum-related materials. The most important difference is that the poles of the daughter cells are different in that one cell has a flagellum and the other has a stalk. Because of the production of two different appearing cells, the growth and division of *Caulobacter* has been described as a model of cell differentiation.

The division cycle of *Caulobacter* can be shown to correspond to that of the standard *E. coli* model by considering that the different DNA patterns are due to the different sizes of the two daughter cells arising by division not occurring in the middle of the dividing mother cell, and that the cell-cycle-specific pattern of expression of flagellum-related genes is related to the completion of poles after the act of cell division. Flagellum synthesis is thus considered a part of surface synthesis. The cycle-specific pattern observed in cells is related more to the window of time in which poles are made rather than synthesis at a particular time during the division cycle (Fig. 7).

9.2 *Bacillus subtilis* Division Cycle

The division cycle of the gram-positive bacterium *Bacillus subtilis* is relatively similar to that of *E. coli*. The major difference between the organisms lies in the fact that the *B. subtilis* cell wall is much thicker (giving rise to its gram-positive character), and this requires an inside-to-outside pattern of peptidoglycan growth. The cell wall is made adjacent to the cytoplasmic membrane, and this wall layer moves out as subsequent layers are made between it and the cytoplasmic membrane. This leads to the multilayered *B. subtilis* peptidoglycan.

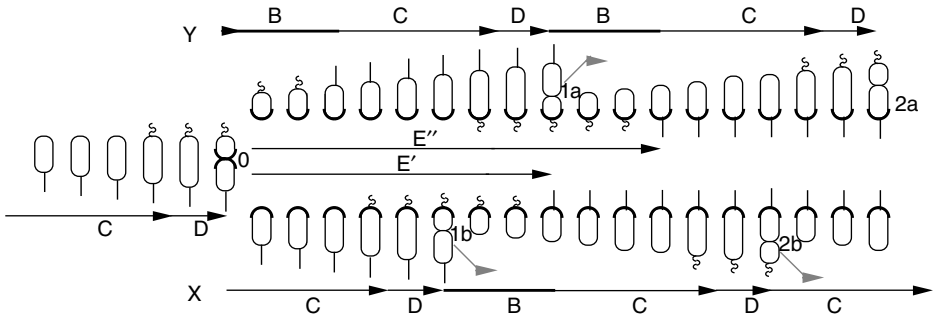

Fig. 7 The *Caulobacter* cell cycle. *Caulobacter* cells divide unequally, producing a smaller swarmer cell that is motile and a larger stalked cell that is generally attached to a surface by the stalk. As drawn here, the development of *Caulobacter* can be followed by concentrating on the two new poles formed by the first division. The development of the poles in both cells is a succession from bald, to flagellated, to stalked. Because the swarmer cell is smaller the development is slightly delayed, suggesting a size control for both the initiation of DNA replication and the completion of pole development. As drawn here, the cell-cycle-specific synthesis of flagella protein (flagellin) is a result of pole development following cell separation. The ultimate end of pole development is a stalk, after which no further changes in the pole occur. Thus, with regard to the general model of cytoplasm synthesis proposed here, the *Caulobacter* cytoplasm (excluding surface) does not exhibit cell-cycle-specific patterns of gene expression.

9.3
Streptococcal Growth during the Division Cycle

The growth of spherical bacteria such as Streptococci reveals a different pattern of surface growth. There is no apparent intercalation of new peptidoglycan material into the preexisting older peptidoglycan. Rather, the old peptidoglycan is conserved and new peptidoglycan grows at the center of the cell to make a completely new cell pole.

10
Mass Increase Is the Driving Force of the Division Cycle

The driving force of the division cycle is cytoplasm synthesis. Some part of the energy used by the cell to make cytoplasm drives the biosynthesis of the cell surface by causing stresses along the cell surface and this stress leads to the breaking of peptidoglycan bonds. The insertion of new peptidoglycan then leads to the increase in cell size. Cytoplasm increase also regulates DNA synthesis. Cell size at birth is greater at faster growth rates (Fig. 3) because the initiation of new rounds of DNA replication occurs when the cell has a unit (or critical) amount of cytoplasm per origin of DNA. Cell size at initiation is proportional to the number of replication points in the cell, and that is why cells are larger at faster growth rates; at faster growth rates there are more origins per cell at initiation. The cell "titrates" the amount of cytoplasm or some specific molecule that is a constant fraction of the cytoplasm. Thus, DNA synthesis is initiated at all available origins when the amount of cytoplasm per origin reaches a particular value.

The cell cytoplasm increases as fast as it can, given the external nutrient conditions. The synthesis of DNA and cell

surface cannot outpace or lag behind cytoplasm synthesis. DNA synthesis cannot go faster because it is waiting to initiate new rounds of DNA replication in response to cytoplasm synthesis nor can it go slower because the cytoplasm would increase without initiating new rounds of DNA replication. Cell surface is made to just enclose the newly synthesized cytoplasm. The regulation of surface and DNA synthesis by cytoplasm thus explains why there is no dissociation of these syntheses during the division cycle and during the growth of a culture. Furthermore, the failure to complete DNA replication (so that a cell has only one genome) prevents cell division; the cell thus ensures that there will be enough material (genome, cytoplasm, and cell surface) to allow the production and survival of two new daughter cells.

11 The Bacterial Growth Law during the Division Cycle

It has been speculated that there is a ''bacterial growth law'' that can be discovered by sensitive methods of analysis. Does the cell grow linearly, bilinearly, exponentially, or perhaps follow some other, yet undiscovered, growth law? If there were a general law of cell growth, independent of the biosynthetic patterns of the three categories that comprise the cell, then the individual categories of biosynthesis would have to accommodate themselves to this overall growth law.

There is no simple mathematical growth law regulating or describing bacterial growth during the division cycle. Bacterial growth during the division cycle is the simple weighted sum of the biosynthetic processes that are described by the three categories proposed here. As presented in Table 1, it can be seen that the components of the cytoplasm of the cell are 80% of the total cell weight. This means that the growth of the cell is approximately exponential. A slight deviation from exponential growth is due to the contribution of cell surface and DNA synthesis. Cell growth, then, is the result of a large number of individual reactions, regulated by local conditions, and not conforming to any overriding growth law.

Tab. 1 Composition of *Escherichia coli*, a typical gram-negative, rod-shaped bacterium.

Cell component	*Molecules per cell*	*Percent dry weight*
Cytoplasm		
Protein	2,350,000	55.0
RNA	255,480	20.5
Polyamines	6,700,000	1.1
Glycogen	4,300	3.5
Metabolites, ions, cofactors		2.5
Surface		
Peptidoglycan	1	2.5
Lipid	22,000,000	9.1
Lipopolysaccharide	1,430,000	2.4
Genome		
DNA	2.1	3.1

If one wished to state the growth law, the growth law is simply the sum of the individual synthetic patterns of the three categories of the cell material.

12
Experimental Analysis of the Bacterial Division Cycle

How can one study the pattern of synthesis of cell components during the division cycle? At first thought, it appears that one could study the division cycle by preparing a synchronized bacterial culture – that is, a culture composed of cells all of the same age, for example, newborn cells – and taking measurements of the cell components at different times during the division cycle. It turns out that this method has rarely, if ever, led to any concrete results. This is presumably due to the introduction of perturbations and artifacts when cells are synchronized, as no naturally synchronized populations are available.

The methods that have given results are nonperturbing, nonsynchrony methods. One is the membrane-elution method, or ''baby machine,'' which analyzes the division cycle of unperturbed cells. In this method, a label is added to a growing culture, the labeled cells are filtered onto a membrane, the cells bind as though bound at one end or pole, and when medium is pumped through the inverted membrane, newborn cells are eluted from the bound cells. Since the newborn cells arise from the bound cells as a function of the original cell age, the first newborn cells arise from the oldest cells at the time of labeling. With time, the newborn cells arise from cells labeled at younger and younger cell ages. By measuring the amount of label per cell during elution, one can determine the pattern of synthesis during the division cycle. This has been done successfully for DNA, plasmids, protein, RNA, peptidoglycan, and cell membrane.

Another method for cell-cycle analysis is flow cytometry, where the amount of material per cell in a cell population is determined for individual cells by a complex system of liquid handling and laser-excitation engineering. The quantitative distribution of cell material can give the relative rate of synthesis during the division cycle. This method has been successful for DNA replication during the division cycle and has confirmed the initial results obtained with the membrane-elution method. It is not clear whether the method is sensitive enough for bacteria to enable the discovery of a particular pattern of DNA replication.

13
Genetic Analysis of the Bacterial Cell Cycle

Complementing the physiological and biochemical analyses of the bacterial division cycle has been a large amount of work on isolating and analysing mutants that affect the division cycle. Because a successful division requires that the cell make all of its required material, a mutation affecting the synthesis of any required material is, in some trivial sense, a mutation affecting the division cycle. Thus, a mutant unable to make a particular amino acid, such as leucine, that is required for growth would stop progressing through the division cycle. However, this would be a trivial relationship to the division cycle because the leucine is required throughout the division cycle and is not related to a specific control mechanism.

More interesting are those mutants that affect the major events of the division cycle

such as the start of DNA synthesis and the start of septation. A large number of mutations affecting these processes have been isolated, and their study has revealed that a number of enzymes and proteins are required for cell-surface synthesis and DNA synthesis.

14
Die Einheit der Zellbiologie

Are the interrelationships of cell-cycle regulation, proposed here for *E. coli*, applicable to other organisms? Other regulatory mechanisms have been proposed in other cell types. For example, a circular regulatory system was proposed for *Caulobacter* and a stochastic mechanism as well as a rate-controlled model for animal cells. Is the mechanism of cell-cycle regulation subject to historical accident? Or is there a unity of mechanisms regulating the division cycle of all types of cells? I conjecture that the *E. coli* model of cell-cycle regulation is generally applicable to other organisms, and that the optimal design of the cell cycle is exhibited by the *E. coli* cell cycle.

In the second decade of this century, Kluyver and his colleagues explicitly proposed the principle of the Unity of Biochemistry, or as originally proposed, Die Einheit der Biochemie (the oneness of biochemistry). Although the original proposal dealt primarily with the nature of oxidation–reduction reactions, the basic principle has evolved to encompass even more unifying principles. The nature of the gene, the genetic code, the mechanism of protein synthesis, the use of enzymes for biochemical changes, the patterns of enzyme regulation, and all of the fundamental aspects of biochemistry appear similar throughout the different organisms on earth. While there are exceptions and unique aspects to many organisms, the essential principle that there is a unified biochemistry has been supported.

Here we must now add, with regard to the cell cycle, the Unity of Cell Biology – *Die Einheit der Zellbiologie* – that is analogous to the Unity of Biochemistry. Phenomena suggesting the existence of other modes of cell-cycle regulation in animal cells have been shown to be consistent with the model for the bacterial division cycle proposed here. For example, the constancy of C- and D-periods is mimicked by the constancy of their analogues in animal cells, the S and G2 periods. The variation in cell size with growth rate and the rules regarding size determination also appear to hold for all organisms. The rules of the cell-division cycle – that is, the logic and design principles of the division cycle – are the same for *Escherichia* and escargot, *Salmonella* and salmon. Although there are many detailed differences between eukaryotic and prokaryotic division cycles, at the deepest level the principle of the Unity of Cell Biology proposes that the division cycle is ultimately regulated by the continuous accumulation of some molecule that is titrated against a fixed amount of another cell component. From this viewpoint, cell-cycle-specific events identified in eukaryotic cells are the result or symptom of a deeper regulatory principle that is produced in a cell-cycle-independent manner. The question for future analysis is whether there is some deeper rule that ensures this common pattern in all cells. I conjecture that this is indeed the case and hope that a search for the underlying meaning of size control in all cells is now the new goal of cell-cycle research.

Keywords

Virulence
The relative ability of an organism to cause disease.

Pathogen
Organisms capable of causing disease.

Adhesin
A molecule used by a bacterial cell to adhere to a surface.

Colonization
The ability of a pathogen to adhere to host cells or surfaces and to multiply within the host.

Quorum sensing
A regulatory mechanism by which the expression of various genes is coordinated to population density via the interaction of a receptor protein and a small organic signaling molecule.

Antimicrobial Resistance
The ability of a bacterial pathogen to become refractory to the actions of a given antimicrobial compound.

Pathogenic Cycle
The common steps that pathogens need to undertake to establish themselves within a host and survive.

The incidence of infectious disease due to bacteria continues to be a leading cause of morbidity and mortality worldwide despite advances in public health measures, modern medicine, and the availability of myriad antimicrobial drugs. Those organisms that are able to cause disease are referred to as *pathogens*. These organisms have evolved many mechanisms to subvert the immune defenses of the human host and usurp usual host cell processes to allow their own proliferation and persistence during infections. In addition to uncovering the inner working of both bacterial and host cells, the elucidation of these processes provides the potential for the development of new therapeutic approaches.

1 Introduction

Despite tremendous advances in medicine and public health measures, infectious diseases caused by microbial agents are still the leading cause of morbidity and mortality worldwide. This is due not only to the emergence of new infectious agents but also to the reemergence of diseases once thought to be under control. Furthermore, increasing numbers of organisms resistant to numerous antimicrobials are being isolated and identified. Organisms capable of causing disease are referred to as pathogens and may be generally divided into three main categories as follows: (1) viruses, (2) bacteria, and (3) fungi and parasites. This chapter will concern itself with bacterial pathogens, and, in the ensuing discussion, we will deal with the strategies used by various bacteria to promote disease. For obvious reasons, most of the discussions will be based on a human serving as the host. However, it should be noted that bacterial pathogens exist for almost every animal and plant life form and that the mechanisms and strategies outlined for survival and causation of disease in the human are also generally applicable to those hosts as well. Bacterial pathogenesis is a large and complex topic and it would be impossible to discuss every detail in a short review such as this. Indeed, there are myriad books that deal solely with this topic, and the reader is directed to these and other publications listed at the end of this chapter for further details. Rather, this chapter is intended to serve as a general overview to provide the basic concepts of this complex field to the reader.

2 Concepts and Principles of Pathogenesis

A concept important to any discussion of pathogenesis is that of virulence, which may be defined as the relative ability of an organism to cause disease. As we shall see, the virulence of a pathogen is intimately tied to a large and complex group of factors (virulence factors, see Table 1) that it can generate and the relative fitness of a given host. The ability of bacteria to be pathogenic is directly associated with the ability of these organisms to produce various cell-associated or extracellular virulence factors. These components are often involved in processes such as adherence to host cells and in the evasion of host defense mechanisms. The presence of these factors allows the bacterium to gain an advantage over the host and results in various pathologies.

To cause disease, some organisms use a combination of tactics, while a few rely on a single approach. Pathogenesis may be caused by factors produced after the bacteria have colonized the host or by factors that are produced exogenous to the host. The latter case, in which the host must contact preformed toxins produced by the bacteria, is primarily limited to certain forms of food poisoning. Interestingly, even though a large number of pathogenic bacteria exist, recent evidence demonstrates that many of these pathogens utilize strikingly similar

Tab. 1 Representative virulence factors/mechanisms and their functions.

Virulence factor/mechanism	*Organism(s)*	*Virulence function*
Motility	*Pseudomonas aeruginosa*	Enhanced ability of motile organisms to disseminate to other tissues.
Altered lipopolysaccharide side chains	*Salmonella typhimurium*	Inhibition of cell lysis by inhibiting the formation of the activated complement complex.
Proteases	*Pseudomonas aeruginosa* *Streptococcus pyogenes*	Destruction of tissue for dissemination; provision of nutrients. Destruction of complement, antibodies, and other host cell defense proteins.
Antigenic variation	*Neisseria gonorrhoeae*	Variation of surface proteins to evade host antibody response.
Exotoxins	A–B types: *Corynebacterium diphtheriae* *Pseudomonas aeruginosa* *Clostridium tetani* *Vibrio cholerae* Membrane disrupting: *Listeria monocytogenes* *Clostridium perfringens*	Killing of host immune response cells (phagocytes, PMNs, etc). Destruction of tissue to enhance nutrient availability and possible dissemination to other sites.
Pili or fimbriae	*Pseudomonas aeruginosa* *Escherichia coli* *Vibrio cholerae*	Adhesion to host cells and mucosal tissue.
Nonpilus adhesins	*Pseudomonas aeruginosa* *Streptococcus pyogenes* *Vibrio cholerae*	Adhesion to cells and mucosal tissue.
Secreted (siderophores) and surface proteins that bind iron	*Escherichia coli* *Pseudomonas aeruginosa* *Yersinia pestis*	Acquisition of iron from host sources.
Capsules	*Streptococcus pneumoniae*	Inhibit phagocytosis. Decrease activation of complement.
Survival within phagocytes	*Salmonella typhimurium*	Evasion of host immune response.

strategies and mechanisms to cause infection and disease. While not applicable in every case, almost all pathogens must successfully complete a series of common steps in order to flourish. First, a pathogen must gain entry into the host. Second, the pathogen must be able to establish itself (colonize) and adhere to host cell tissues. Third, the pathogen must be able to survive within the host. Fourth, the pathogen must be able to cause cell or tissue damage. Lastly, the pathogen must be able to disseminate from the host in order to infect a new host.

The process may appear to be simple, but one must remember that pathogens face considerable challenges in attempting to complete the steps outlined above. Almost immediately these organisms face the task of outcompeting the normal

microbial flora that may be present at a given infection site. There is competition for nutrients and adherence sites, and many microbes considered part of the normal flora are able to defend their territory via the production of various proteases, toxins, and other deleterious factors. If a bacterium can survive this challenge, it must then face the formidable challenge of trying to evade the human immune system.

Clearly, in order to survive, a pathogen must be able to respond and adapt to its changing environment. Pathogens must adapt to changes induced during transmission to a new host or to changes that occur in the new host as a result of the pathogens' presence. The fact that many successful pathogens have been identified is a testament to the adaptability and diversity of these organisms. The concept of adaptability raises the point that we must recognize that pathogenic bacteria do not cause disease with malicious intent as is so often implicitly conveyed in any such discussion. Rather, they cause disease as a consequence of the evolutionary stresses that select for those organisms that can survive in an environment that is most often very different from the environment in which they are usually found. As will become evident, the balance between host and pathogen is quite delicate and a small shift in this balance can give one or the other the upper hand.

3 What Makes a Pathogen a Pathogen?

Bacteria cover and colonize most of the exterior surface of the body including mucosal surfaces. While the majority of these organisms usually serve a beneficial role to the host, or at least do not appear to be detrimental, a small percentage of bacteria are pathogenic. This demonstrates that the association of pathogen and host does not always lead to disease. In fact, some pathogens such as *Streptococcus pneumoniae* are able to colonize the host in large numbers; yet the host does not exhibit signs of streptococcal pneumonia. The number of organisms needed to be present to prove sufficient to cause disease is termed an *infectious dose*. The specific infectious dose can vary between organisms and even for the same organism in different hosts. Some pathogens are considered ''overt'' in that they can cause disease even in immunocompetent individuals. Other pathogens are considered ''opportunistic,'' causing infection only when some predisposing factor is present in the host. A classic example of an opportunist is *Pseudomonas aeruginosa*, which infects individuals who have been immunocompromised in some way.

The finding that a small percentage of organisms can actually be pathogenic leads us to the question of what makes a given organism a pathogen. The rise of molecular biology and advances in genetics allowed us to gain an appreciation for the complexity of the answer to this question. Clearly, the susceptibility of the host plays a large role in the success of a pathogen, and there is evidence (discussed further in this chapter) that specific genetic traits of the host may predispose an individual to a given infection. Just as clear is the fact that the genetic makeup of the bacterium itself plays an equally important role. Closely related bacteria can demonstrate dramatically different pathogenic potential. This is evident with the identification of specific strains of organisms that are pathogenic, while other strains of the same organism are not.

In the genetic sense, a bacterium can become pathogenic by one of a number of events. The organism could harbor genes unique to itself. A good example of such genes is the ''pathogenicity islands'' (PAIs) that have been identified in numerous species of bacterial pathogens. PAIs are chromosomal segments of DNA that encode genes required for the expression and production of virulence factors and that are absent from nonpathogenic related bacteria. The PAIs can range in size from 10 to 200 kb and thus can encode few or many genes important for virulence. Many of the identified PAIs are located between loci that encode transfer RNA, sites that are frequently used by specific bacteriophages as integration sites. This finding suggests that the acquisition of a PAI by a given organism can be accomplished simply by the infection of the bacterium with a phage harboring the DNA as part of its genome. This horizontal gene transfer concept is further supported by the finding that PAIs are usually flanked by direct repeat sequences that indicate that the region is prone to recombination events such as those necessary for the integration of a foreign fragment of DNA. Further evidence for the concept that the PAI is acquired from a different organism is that they often exhibit G + C contents that are significantly different from that of the organism in which they are found. Implicit in this finding is that transfer of a PAI between organisms could be accomplished simply by infection with a bacteriophage that is able to infect both organisms.

It should be noted that PAIs are not the only virulence elements that can be acquired by horizontal transfer. For example, many of the genes required for the virulence of *Shigella spp.* are maintained on a large plasmid carried by the pathogenic strain. *Shigella* is also able to produce a number of cytotoxins, the genes for which are carried by a bacteriophage that has integrated into the chromosome. This bacteriophage has also been shown to be transferred to the enterohemorrhagic strains of *Escherichia coli*, which are now able to produce the cytotoxins. Thus, the transfer of genes encoding virulence factors within the same specie or between species has been documented and provides a mechanism for the acquisition of virulence capabilities by organisms that were previously avirulent.

A second mechanism by which a bacterium can evolve to pathogen status is via the loss of a function required for suppression of virulence factor expression. Suppressors, as the name implies, function to maintain the expression of a given gene(s) quiescent. One of the first examples of such a mechanism was the loss of the OmpT surface protease of *Shigella*. This protease suppresses virulence since its expression interferes with the expression of the VirG protein, which is required for intercellular spread. The regions of DNA corresponding to the genes that have been lost are known as *black holes* to contrast them with the PAIs whose acquisition leads to increased virulence.

A bacterial species may become more virulent by the differential regulation of the same group of genes. That is, the expression of the same functional group of genes may be regulated by different environmental controls. An excellent example of such differential regulation occurs again in the genus *Shigella*. Both *S. enterica* and *S. flexneri* harbor very similar genes encoding functions required for cellular invasion. However, the *S. enterica* genes respond to oxygen tension, while the expression of the *S. flexneri* cohort of genes is modulated by temperature.

Finally, a bacterium can increase its virulence simply by harboring mutations in a gene required for pathogenic success. There are numerous examples of such a mechanism in action, but one of the best is the *fimH* gene of *E. coli*, which encodes a protein required for adherence to host tissue. It has been shown that various single mutations in the sequence of this gene can give rise to variants of the adhesin, which increase the binding of the *E. coli* to tissue, thereby raising its virulence potential.

Clearly, the mechanisms described in the preceding text have implications for the evolution of pathogenic bacteria. A given organism may be the subject of one or more of the mechanisms and may thereby evolve into a more potent, efficient, and ever-changing pathogen. In addition, the ability of vectors such as bacteriophages and plasmids to harbor virulence genes and their potential as vectors for horizontal transfer of virulence traits suggests that bacteria are constantly evolving during passage through their hosts.

4 Regulation of Virulence

As mentioned in the previous section, pathogens produce an array of products collectively termed *virulence factors*, which enable them to cause disease. However, pathogens do not express these factors constitutively. Rather, expression of most virulence factors is tightly controlled. Given that a pathogen must be able to sense the condition of its host, it is not surprising that many of the signals that initiate expression of virulence factors are environmental. Diverse bacterial pathogens can recognize an array of signals including pH, temperature, growth phase, osmolarity, oxygen tension, and availability of iron and carbon source as cues for virulence factor expression. By way of example, the Anr protein is responsible for the modulation of gene expression due to oxygen availability in *P. aeruginosa*. There are a number of regulatory factors that are responsive to the presence or absence of iron. The most recognized of these is the Fur protein that binds to specific DNA elements only in the presence of iron, resulting in the repression of the target gene(s). The ability to sense such signals is critical to the organisms' ability to adapt to the microenvironment in which it finds itself.

The sensing of a specific signal results in the triggering of a cascade of events that lead to a regulation of the genes responsible for the production of a given virulence factor(s). The signals are converted to a specific response via the action of molecules deemed regulators. In the simplest sense, the regulators alter the expression of a gene so that it is either increased or decreased in response to the signals that are sensed. Some of these regulatory molecules may respond to more than one signal, and, in this way, the expression of various virulence factors is coordinated and made interdependent to allow the required response of the organism. While the mechanism(s) used to regulate gene expression are numerous, they can be broadly categorized into several common motifs. In addition, a pathogen can use one or more mechanisms to simultaneously respond to the signals that they sense. Furthermore, one or more mechanisms may act to regulate the production of a single virulence factor, allowing the pathogen to monitor and respond to multiple environmental cues to finely tune the expression of the given factor. Although many diverse organisms

use a variety of regulators, many of these regulators can be grouped into families on the basis of their function. Thus, although homologies at the sequence level (both nucleotide and protein) may occur, functionally the products are the same. The number of regulators identified has exploded with the introduction of molecular techniques and their application to studies of bacterial pathogenesis. While all of them cannot be discussed here, it is important to acquaint the reader with some examples and hence three major regulatory mechanisms are briefly described in the following text.

One of the simplest ways to regulate the expression of a specific gene is to alter the recognition of the promoter elements recognized by RNA polymerase (the enzyme responsible for synthesis of RNA from DNA). Sigma factors, synthesized by most bacteria regardless of pathogenic potential, are proteins whose function is to interact with RNA polymerase and thereby alter the expression of a given gene(s). Many organisms express various sigma factors, which are responsible for coordinating gene expression to various specific environmental cues. Not all organisms will produce the same sigma factors, but the role of sigma factors as regulators of gene expression has been well documented in many bacteria. These factors may be produced during specific periods of growth of the organism or in response to specific stimuli. One excellent example is the sigma factor RpoS (also known as σ^{32}). This sigma factor has been shown to be important for the virulence of a number of organisms including *E. coli*, *Salmonella typhimurium*, and *P. aeruginosa*. RpoS is expressed during the stationary phase of growth when the organism is under various stresses such as nutrient deprivation and oxygen tension. Other sigma factors, which have a demonstrated role in the expression of virulence genes, are RpoE, which responds to various stresses and is important for the virulence of *S. typhimurium*; and RpoH, which is involved in the heat shock response of many organisms. The production of the exopolysaccharide alginate, responsible for the mucoid phenotype of *P. aeruginosa* in infections of individuals with cystic fibrosis, is regulated by two sigma factors RpoN and AlgU.

One of the most common types of regulator is that which belongs to the two-component systems. These regulatory systems consist of two proteins – a sensor protein, which is embedded in the membrane of the bacterial cell wall and which acts to sense specific signals; and a response regulator, which is then the mediator of the regulatory response. The sensor molecules usually contain a histidine kinase function that allows the molecule to phosphorylate itself when a specific signal is sensed. The phosphate is then transferred to the response regulator, which alters its conformation and leads to the formation of an ''active'' form of the molecule. The response regulator may then either interact with the RNA polymerase enzyme or bind to the promoter region to result in stimulation or repression of the gene of interest. Two-component systems are involved in the sensing of and response to signals such as iron availability, carbon and nitrogen levels, and phosphate levels. The expression of many different virulence factors is known to be regulated by two-component systems. Among these are the *Bordetella pertussis* toxin, fimbriae and filamentous hemagglutinin Fha (controlled by the BvgA/BvgS system), the formation of pili and toxin in *Vibrio cholerae* (the ToxR/ToxS system), and

alginate production in *P. aeruginosa* (the AlgZ/AlgR system).

In addition to the two-component systems, a number of other regulatory factor families have been implicated in virulence factor regulation. The families are usually based on the homology or conservation of distinct motifs (e.g. the ability to bind a specific DNA element) within the members of the group. Two of the best-characterized are the AraC and LysR regulator families. The AraC regulators are a group of proteins that exhibit homologies to the AraC protein, which regulates arabinose utilization in *E. coli*. These proteins bind to specific DNA sequences upstream of target genes to regulate their expression. A member of the AraC family, the VirF protein of *Yersinia spp.* is involved in regulating the expression of the Yop proteins, which are involved in the virulence of this organism. It should be noted that the expression of VirF itself is regulated by temperature and that the Yop proteins are only expressed at 37 °C, demonstrating the networking of different regulatory mechanisms to produce expression of the correct product at the correct time during infection. The LysR family includes SpvR, a DNA-binding protein that regulates the expression of a number of genes required for the survival of *Salmonella spp.* in the mouse.

Over the past decade, a strong connection has been made between the coordination of population density and the regulation of virulence genes in a mechanism known as *quorum sensing*. This coordination is achieved by the interaction of small organic signal molecules, which can traverse the bacterial cell wall, with specific receptor proteins that can act as regulators of transcription. In gram-negative organisms, the signals appear to be primarily homoserine lactones, while gram-positive organisms appear to use peptides. It is proposed that as cell population density increases, the concentration of the appropriate signal molecule increases both external and internal to the bacterial cell. Within the pathogen, the number of regulator/signal complexes is increased until, upon reaching a threshold concentration, gene expression is coordinated. The discovery of this mechanism in pathogens is relevant to the observation that many pathogens must reach a critical density within the host prior to causation of disease. It is postulated that quorum sensing is used by pathogens to allow production of virulence factors at the appropriate time during infection and that the pathogen can unleash an arsenal of factors to overwhelm the host. As an extension of this postulate, it may be proposed that a pathogen does not express unwanted factors too early, a situation that, in addition to being wasteful, may also give premature warning of the pathogen's presence to the immune system. The field of quorum sensing is intensively studied, and the list of pathogens that use such a mechanism as well as the virulence factors regulated by this mechanism is rapidly expanding.

5 The Pathogenic Cycle

In the previous section, there was a discussion of the steps that most pathogens undertake in their progression to causing disease. In the sections that follow, these steps will be described to allow the reader to gain some appreciation of the complexity of the process as well as to gain some insight into the hurdles that pathogens face within the human host.

5.1 Transmission of Pathogens to the Host and Host Susceptibility

The information regarding the effective transmission of a pathogen to its host is somewhat limited. Some pathogens such as *B. pertussis*, the causative agent of whooping cough, can be transmitted via aerosols created by sneezing. Others, including *Treponema pallidum* and *Neisseria gonorrhoeae*, which cause syphilis and gonorrhea respectively, are transmitted via sexual contact. Some organisms rely on transmission via animal or arthropod vectors. *Borrelia burgdorferi*, the cause of Lyme disease is transmitted by the deer tick, which can bite humans and in effect inoculate them with the organism. Still others, such as *V. cholerae*, are internalized by ingestion of contaminated matter or via the fecal–oral route.

Within the host, any available surface is a potential target for bacterial attack. However, not all pathogens can interact with all surfaces or, for that matter, infect all hosts. Some pathogens may be able to interact with a wide variety of cells and tissues, whereas others are restricted to specific cell types. This demonstrates that some microorganisms exhibit preferences for specific tissues and hosts. For example, *N. gonorrhoeae* can only infect humans and more specifically only certain mucosal surfaces. In contrast, *P. aeruginosa* can cause a wide variety of infections affecting various tissues in a number of hosts.

There is increasing evidence that some factors may predispose a given host to infection with a given pathogen and that the severity of the disease may actually be modulated by these factors. A prime example is the NRAMP1 protein, which was initially identified in mice but which has also recently been identified in humans. This protein is located on the surface of macrophages, cells that are part of the immune system and that are used to engulf bacteria and destroy them, where it functions as a transporter of specific metals such as iron and manganese into the mammalian cell. Mutation of this protein leads to increased susceptibility to infection with organisms such as *Mycobacterium spp*. A single amino acid mutation (glycine at position 169 changed to aspartate) is highly associated with this increased susceptibility. It is proposed that the loss of proper function of this protein results in increased levels of such metals in the extracellular spaces. Since these metals are essential for the basic growth requirement of all cells including bacteria, it is proposed that the increased availability of the metals allows the pathogens to thrive in an environment in which these metals would normally be limited in supply. Furthermore, since the metals are used by bacteria as integral components of enzymes required to defend against host defenses, the availability of the metals in NRAMP1 mutant hosts would allow the organisms to resist those defenses and survive.

5.2 Entry into the Host

The primary barrier to infection is the epithelium, which is considered part of the human hosts' innate immunity. Bacteria may breach this protective layer in many ways. One approach is to enter through breaks in the skin caused by trauma, including cuts, burns, and insect bites. *Pseudomonas aeruginosa* is an opportunistic pathogen that can cause horrific infections of individuals who suffer burn trauma. Arthropod vectors can transmit *Yersinia pestis*, the causative agent of the

bubonic plague, via direct inoculation in the form of a bite. The increased use of indwelling medical devices such as catheters also provides portals of entry into the host and may actually serve as recurrent sources of infection. Additional routes of entry include mucosal surfaces, which are involved in nutrient uptake or gas exchange. Examples of such surfaces are the gastrointestinal and respiratory tracts. These mucosal surfaces are in constant contact with the external environment and hence are under risk of being breached by bacteria. These tissues serve as a thin barrier between the host and the external environment and provide a portal of entry for many bacteria that are capable of invading a host through intact epithelia. The breach of the skin barrier is important because it allows not only the normal flora on the surface to enter but also invites invasion by pathogens. Indeed, organisms that are relatively innocuous on the surface of the skin may actually present problems if allowed to penetrate the skin barrier and gain access to underlying tissue or blood vessels.

Some organisms do not directly enter the host nor require a living vector system to cause disease. Although they can also cause wound infections, members of the genus *Clostridium* can elaborate toxins in foodstuffs that can result in severe disease upon ingestion. One of the most common examples of disease without colonization is botulism. *Clostridium botulinum* is able to produce botulinum toxin that essentially acts as a neurotoxin. Upon ingestion of tainted food, the toxin is absorbed from the intestines into the circulation and binds to susceptible neurons. Part of the toxin (i.e. the light chain) is internalized in the cytoplasm of the neurons where it begins to exert its proteolytic activity and disrupt cellular pathways required for the release of chemical messenger molecules. As a result, the muscles do not receive the proper signals and essentially enter a state of flaccid paralysis. As the paralysis progresses further, there is risk of fatal respiratory and cardiac failure.

5.3 Adherence to Host Cells

Once inside a host, bacterial pathogens can adhere either directly to a host cell surface or to a component of the extracellular matrix, which functions as a foundation for the host cells. Some pathogens remain on the surface of a cell and multiply at that location, while others make use of their ability to invade the tissue in search of a more suitable location. Nonetheless, even invasive organisms must initially attach to a host cell. This is a key step in the interaction between the pathogen and the host. Implicit in this interaction is that the organism must possess a molecule that can allow it to adhere to a host and that the host must possess a receptor for the bacterial adhesin. The surfaces of attachment can be the skin, the mucosal membranes, and some of the deeper tissues. The host has evolved mechanisms such as coughing, sneezing, secretion of saliva, and mucus flow in an attempt to wash away the bacteria. However, some pathogens are able to strongly attach themselves and prevent their eradication from the host. These organisms utilize specific components, termed *adhesins*, to adhere themselves to receptor sites on the host cell surfaces.

The types of adhesins used by bacterial pathogens are varied. They may be composed of either proteins or carbohydrates. The protein adhesins are generally separated into two groups known as fimbrial (pili) and afimbrial. Those adhesins

that consist of carbohydrate are generally components of the bacterial cell membrane, wall, or an exopolysaccharide coating known as the capsule. Many organisms are believed to use a two-step process in which an initial loose binding is mediated by adhesins such as pili followed by a tighter binding owing to the action of other adhesins. This demonstrates that it is common for a single pathogen to synthesize and utilize more than one adhesin.

The function of an adhesin implies the presence of a receptor for that adhesin. The variety of molecules that can be used as receptors include proteins of the host cell membrane, glycolipids, glycoproteins, and proteins that make up the extracellular matrix such as fibronectin and collagen. In some cases, the pathogen can even inject its own receptor into the host, have it located to the surface, and then use it to bind to the host cell. This appears to be the mechanism used by enteropathogenic *E. coli*.

The best-understood adherence mechanism is the use of protein structures known as fimbriae or pili. These rodlike structures are composed of protein subunits termed *pilin*, which are arrayed and extend outward from the surface of the pathogen. In some organisms, the pili are distributed over the entire surface, while in others the pili are localized to a preferential location on the surface. In some cases, the tip of the pilus mediates the actual adherence. This is accomplished by a very specific binding of the pilus to a molecule on the host cell surface. The host cell receptors are most often carbohydrate residues that are part of glycoprotein or glycolipid molecules. The specificity of the binding to these host receptors is significant in determining where, within the body, the organism will eventually bind, since some receptors may be tissue-specific. In some cases, the specificity of binding is determined by a special tip structure that consists of several proteins different from pilin. In others, it appears that pilin itself is involved.

The synthesis and assembly of pili is a complex process that requires proteins other that those involved in the actual pilus structure itself. Usually, the tip of the pilus is assembled and secreted into the periplasm, where specialized proteins known as chaperones hold the pilus proteins in the proper conformation for the addition of further pilin subunits and the eventual transport of the growing pilus to the outer membrane. Pilin subunits are added to the base of the pilus molecule until the proper length is reached. The signals involved in determining the proper length of the pilus are not understood. It is known that a periplasmic protein is involved in signaling for the end of pilus synthesis, but the mechanism by which it conveys this information is still a mystery. There are numerous families of pili that use diverse mechanisms of biogenesis and that have distinct structural characteristics.

Attachment is especially important in areas such as the mouth, the intestinal tract, and the bladder, which are washed by fluids. In these areas, only organisms capable of adhering will be capable of persisting. One of the most obvious of these sites is the urinary tract, which is subject to washing by urine. A number of the adhesins of uropathogenic *E. coli* strains have been identified and studied. Several pilus types have been identified. The type 1 pili appear to be involved in the colonization of the vaginal tract; however, the contribution of these pili in bladder infections appears to be minimal. The P pili, synthesized by the products of the *pap* (*p*yelonephritis-*a*ssociated *p*ili) genes, are extremely important in strains that

cause kidney infections (pyelonephritis). Although P pili of many antigenic types exist, they all appear to have the same type of receptor (globobiose).

As mentioned above, surface molecules that are important in adherence but which do not form a piluslike structure are often called the *nonpilus adhesins* or *afimbrial adhesins*. In addition to the fimbrial adhesins, the uropathogenic *E. coli* strains also carry adhesins that are not pili. These adhesins include the afimbrial adhesins Dr, AFAI, and AFAIII. It is proposed that these molecules are responsible for the tighter binding of the bacterium to the host cell surface subsequent to the initial binding by the pili. Very little is known about the structure and functions of these types of molecules, but it appears that some of them may recognize host cell surface proteins rather than carbohydrates. Many pathogens maintain several alternative means of adhering to cells that may be used under specific environmental conditions or to allow attachment to specific cell types. Members of the genus *Yersinia*, including *Y. enterocolitica*, *Y. pestis*, and *Y. pseudotuberculosis*, produce a number of adhesins that have also been implicated in the invasion of host cells. These adhesins (Inv, Ail, PsaA, and YadA) are extremely interesting in that their expression is often temperature-dependent and, in most cases, they do not appear to use the same receptors. Both the Inv and YadA proteins are expressed at 37 °C and both are capable of using β1-integrins as their receptors. However, YadA can also bind to laminin and fibronectin. In addition, the gene for Inv is chromosomally located, whereas the gene for YadA resides on a large plasmid carried by the organism. In contrast, Ail can be expressed at both 30 °C and 37 °C (albeit expression is higher at 37 °C) and although its receptor has not been identified, it does not appear to be the β1-integrins. PsaA is interesting because it is expressed in both *Y. pseudotuberculosis* and *Y. pestis* but not in *Y. enterocolitica*. Moreover, in contrast with all the other adhesins, it appears to be a pilus. It is expressed only at 37 °C and only when the pH is below 7.

Bordetella pertussis, the causative agent of whooping cough, provides an interesting case for studies of the specificity of adherence. *Bordetella pertussis* exhibits an extraordinary preference for ciliated cells of the respiratory tract. These organisms produce a number of adhesins of which the two best studied are the filamentous hemagglutinin (Fha) and pertussis toxin (Ptx). Both adhesins lack the characteristic ordered structure of a pilus. The receptors for Fha are the galactose residues of sulfated glycolipids. Part of the preference for the ciliated respiratory cells may be due to the high content of a type of sulfated glycolipid known as sulfatide in the membranes of these cells. Mutants in Fha are still able to colonize the host, indicating that other adhesins are present.

The Ptx molecule is capable of functioning both as a toxin and an adhesin. Ptx is composed of six subunits termed S1 to S5, all of which are present in single copies except for S4, which is present in two copies. During an infection, some of the toxin molecules are secreted into the surrounding environment, but the rest remain attached to the bacterial cell surface. These attached Ptx molecules can now function as adhesins. The S2 and S3 subunits are responsible for binding to receptors on the host cell. It is proposed that these molecules act as adhesins when they are left on the bacterial cell surface.

Even though both these molecules have a high degree of homology at the amino acid level, they appear to bind two different receptors. S2 specifically binds to a glycolipid called *lactosylceramide*, which is found primarily on ciliated respiratory cells. S3 binds to a ganglioside found primarily on phagocytic cells. It should be noted that Fha can also bind CR3 on polymorphonuclear monocytes. *Bordetella pertussis* also produces pili and a surface protein known as pertactin.

Some organisms use polysaccharide-based adhesins to attach to host tissue. These adhesins are exemplified by the teichoic acids (components of the gram-positive bacterial cell wall), lipopolysaccharides or lipooligosaccharides (found only in gram-negative organisms), or capsules (found on both gram-positive and negative organisms). As examples, both *Staphylococcus* and *Streptococcus spp.* utilize their teichoic acids as adhesins; *Haemophilius influenzae* makes use of lipooligosaccharides to attach to respiratory epithelial cells; and adhesion of *Mycobacterium spp.* is promoted by the glucan and mannan polysaccharides found in their capsule.

A little-discussed facet of adherence is the role that the host cell itself may play in aiding the attachment of the pathogen. It is known that interactions with pathogens activate various host cell–signaling systems. Recent data suggest that pathogens may be able to connect to these signaling mechanisms to encourage the host cell to synthesize receptors to facilitate bacterial adherence. Recent data suggest that various enteropathogenic *E. coli* may secrete proteins that stimulate the expression of specific receptors on host cell surfaces. The *E. coli* then utilizes these receptors for adherence. *Streptococcus pneumoniae* has also been shown to stimulate host cells to express a receptor for its adherence.

5.4 Evasion of the Host Immune Response

After attachment, the bacteria must survive in their new environment. Toward this end, the bacteria must compete for nutrients not only with the host but also with the indigenous microbial flora. In addition, the organism must be able to evade the components of the host immune response. Antibodies and complement are the major components of the humoral response and when these proteins encounter a pathogenic organism or its soluble components, the antibodies bind to form an antibody–antigen complex. In the case of whole organisms, a series of complement proteins bind the complex and result in the lysis and death of the pathogen. Some pathogens (e.g. *S. typhimurium*) exhibit serum resistance in that they are able to inhibit the formation of the complement complex and thereby avoid cell lysis. In the case of soluble factors, the formation of the complex makes it easy to phagocytize and remove pathogens by specific cells. However, the formation of the immune complexes themselves may cause pathology as seen in complex-mediated hypersensitivity in which the host immune system is turned against the host itself. An excellent example is the case of post-*Streptococcal* glomerulonephritis. The classic view of this disease postulates that lysis products of *Streptococcus pyogenes* that result from the host inflammatory response attempting to clear a throat infection eventually enter the bloodstream and initiate an antibody response. The high levels of antibodies produced by the host then interact with antigens present in the bloodstream, resulting in the formation of antibody–antigen complexes, which may then accumulate in the kidney. The complexes themselves may

elicit an inflammatory response resulting in damage to kidney tissue and eventually impairment of normal kidney function. The same organism is also responsible for rheumatic heart disease in which antibodies directed against a number of *S. pyogenes* products include those against M protein, a cell surface protein of *S. pyogenes* that shares epitopes with proteins on the surface of cardiac tissue. Hence the formation of antibodies against M protein results in the production of a set of antibodies that may also recognize the host tissue, leading to an immune response against the host.

Alternatively, the interaction of pathogens with antibodies may make them more susceptible to phagocytosis. The process of coating cells with antibodies termed *opsonization* leads to their recognition by phagocytic cells and other cells of the immune system. This interaction may also lead to hypersensitivity reactions since many of these cells will release molecules that result in the development of an inflammatory response. Some pathogens directly attack the immune response (e.g. *P. aeruginosa*) by producing proteolytic enzymes that can degrade certain classes of antibodies and complement components. Others evade the immune response by cloaking themselves in exopolysaccharide capsules (e.g. *Klebsiella pneumoniae*, *H. influenzae*), which are believed to impair the ability of antibodies to bind and to prevent phagocytosis, or by periodically changing their surface antigens to render existing antibodies ineffective (antigenic variation). *Neisseria gonorrhoeae*, the causative organism of gonorrhea, provides a good example for antigenic variation. This organism is capable of using a variety of methods in order to vary the amount and composition of the pili on its surface. In this way, it presents an ever-changing surface to the host response, resulting in a decreased ability of the host to clear the organism. Still other organisms utilize a process of molecular mimicry in which they present a surface marker that the host recognizes as "self" and thus does not respond with a normal immune response. Good examples of this mimicry are the hyaluronic acid capsule of *S. pyogenes* or the sialic acid capsule of *N. meningitidis*. The importance of evading the immune response is illustrated by opportunistic pathogens that are limited to immunocompromised hosts but cannot survive in a host whose immune system is intact.

5.5 Invasion and Intracellular Survival

In order to persist and perpetuate the infection, some pathogens need to gain access to deeper regions of the host through a process generally known as invasion. The ability of pathogens to invade normally phagocytic cells such as the macrophages, which function to engulf pathogens, is not very surprising. However, pathogens have had to evolve more elaborate mechanisms in order to invade nonphagocytic cells. The fact that some invasive pathogens can invade an extremely diverse population of cells while others are restricted to specific cell types implies that host cell receptors are important in invasion. Integrins that play a role in host cell interactions including attachment, phagocytosis, and the binding of proteins present in the extracellular matrix have been identified as receptors. *Yersinia pseudotuberculosis*, *Mycobacterium tuberculosis*, and *Legionella pneumophila* have all been shown to utilize members of the integrin family of proteins as receptors.

In actuality, the concept of invasion can be subcategorized into two types, extracellular and intracellular. In extracellular invasion, a pathogen breaches the barriers of various tissues in order to disseminate within the host but in a manner in which it does not actually enter the host cells. Some organisms (e.g. *P. aeruginosa* and *Staphylococcus aureus*) produce and secrete enzymes that degrade host cell molecules such as elastin, an extracellular protein, and hyaluronic acid, the cement that holds cells together. Destruction of these molecules allows the organism to move from one location to another more suitable location where they can survive and proliferate.

Many pathogens, both gram-positive and gram-negative, have the ability to invade intracellularly. In fact, some pathogens such as *Chlamydia spp*. and *Rickettsia spp*. are obligate intracellular pathogens and absolutely require a host cell for growth. Other pathogens are classified as facultatively intracellular and invade host cells to proliferate or to spread to other tissues. The advantage of intracellular invasion is several-fold. First, it sequesters the organism from the potentially lethal effects of the host immune system. Second, it places the organism in an environment that is nutrient-rich. Lastly, it positions the organism in a location where competition from other organisms is almost nonexistent. However, invasion requires a set of complex biological mechanisms that must allow the organism a means to not only enter the cells but also survive, multiply, and eventually disseminate from the target tissue. Intracellular invasion can also be subdivided into two types. There are those pathogens that take advantage of the ability of highly differentiated professional phagocytes, which normally ingest bacteria. Other pathogens are able to invade cells that do not have the ability to ingest bacteria. In this type of invasion, the process is considered directed. That is, the bacterium directs the production of various factors known as invasins or internalins that allow the organism to invade. One example of such a pathogen is *Y. pseudotuberculosis*. This organism utilizes invasins including the Inv and YadA products to associate with the β1-integrin on the host cell surface. The association with multiple receptors leads to the bacterium becoming literally enveloped by the host cell and thus internalized. The process has sometimes been referred to as a *zippering* on the basis of the obvious structural analogies as the host cell surrounds the bacterium. In contrast, *Shigella spp*., which are also intestinal pathogens, utilize a different approach involving the temperature-sensitive induction of Mxi–Spa and Ipa products. Immediately following ingestion, the cells begin to synthesize the Mxi, Spa, and Ipa products owing to the temperature of the host. The Mxi–Spa products assemble in the membranes of the organism and form a translocation apparatus that is used to move the Ipa proteins out of the cell once contact with the host cell has been made. The Ipa proteins form complexes that interact with the host cell surface and alter the signaling pathways of the host cell. The altered signaling results in rearrangements of the host cell cytoskeleton and leads to the formation of membrane projections giving the host cell a ''ruffled'' appearance. Eventually, the projections of the membrane encircle the *Shigella* and the organism is taken into the cytoplasm of the host cell. It should be noted that some pathogens make use of both extracellular and intracellular mechanisms of invasion in order to proliferate.

Once inside a cell, there are a number of possible outcomes for the pathogen. The

majority of the cells that enter a phagocytic host cell are destroyed. However, some pathogens have evolved mechanisms that allow them to survive within this environment. For those pathogens that do not invade professional phagocytes, the task of survival is somewhat facilitated in that their host cells do not maintain an arsenal of host defense mechanisms as do the phagocytes. Survival within host cells is accomplished by a number of strategies. Upon ingestion of the pathogen, the host cell stimulates fusion of the vacuole harboring the pathogen (endosome) with vacuoles that contain degradative enzymes (lysosomes). Some organisms such as *Mycobacterium spp*. are able to inhibit the fusion of the endosome to the lysosome, thereby eluding the toxic enzymes. Other pathogens (e.g. *Rickettsia* and *Listeria monocytogenes*) are able to dissolve the endosomal membrane and escape directly into the cytoplasm of the cell. Still others (e.g. *L. pneumophila*) utilize outer-membrane proteins designated Mip that interact with specific receptors on the host cell surface to stimulate engulfment via pathways that expose the pathogen to fewer killing mechanisms. As an added benefit, *L. pneumophila* is also able to inhibit the fusion of the endosome to the lysosome.

5.6 Dissemination

Many pathogens remain localized to the initial site of attachment, while others are capable of dissemination within the host. The ability to disseminate allows the pathogen to move to environments of greater nutrient availability as well as to increase the probability of locating a preferred niche (see preceding text). Dissemination may involve movement through cells or between cells in the extracellular matrix. Many pathogens are capable of eroding tissue through the secretion of extracellular products. *Pseudomonas aeruginosa* and *Staph. aureus* may secrete a large number of extracellular products including toxins, which can have an exfoliative effect, and collagenases and elastases, which degrade major connective tissue components. *Listeria monocytogenes* can take intracellular invasion one step further to aid in dissemination. This organism makes use of various virulence factors, including a membrane-disrupting toxin known as Listeriolysin O, and phospholipases to escape from the endosome into the cytoplasm. Once in the cytoplasm, it begins to disrupt normal cellular processes, resulting in the deposition of actin on the bacterial cell surface. These ''actin tails'' are further extended and the organism uses these tails to move about. The reorganization of the host cell cytoskeleton also permits the formation of ''philopodia'' or extensions of the infected host cell. By moving through these philopodia, the pathogen can gain access to neighboring cells and invade them. In this manner, *Listeria monocytogenes* is not required to exit the host cells and remains protected from the host immune defenses.

6 Resistance to Antimicrobials

The increasing resistance of many bacterial pathogens to a wider range of antimicrobial agents is an intriguing yet alarming observation. Clearly, the increased use of antibiotics by the medical profession has contributed to the problem by placing pressure on bacterial populations to select individual cells that can survive in the presence of these agents. As a result,

the concept of many agents as ''wonder drugs'' is quickly fading and is being replaced with the reality that we may, if we have not done so already, be selecting for ''super organisms'' resistant to all available drugs. By way of example, strains of methicillin-resistant *Staph. aureus* have been identified, and for those unfortunate individuals who are infected by such strains, there are no viable antimicrobial options available. Aside from the purely scientific standpoint, an understanding of how pathogens become resistant to antimicrobials is quickly becoming an area of intense research owing to the global threat that such super organisms would pose.

In general, there are several mechanisms that would lead to the acquisition of resistance to an antimicrobial.

Alteration of the target. An organism could evolve to select for those individuals who have altered the target of the antimicrobial so as to render the target insensitive to the drug. This is seen in a number of cases including the transpeptidases, which are enzymes involved in bacterial cell wall synthesis and are normally inhibited by penicillins by virtue of the fact that they are capable of binding the drug. Single amino acid changes within the protein structure of these molecules can render them insensitive to the drug altogether or merely reduce their binding affinity for the drug so as to decrease their sensitivity. Other antimicrobials target the ribosomes, molecules essential for protein synthesis by the cell. Single mutations within subunits of this molecule can also render it insensitive to various drugs such as spectinomycin.

Overproduction of the target. While not a common mechanism, bacterial pathogens could overproduce a target and effectively increase the amount of drug required to be effective.

Modification of the antimicrobial. This is a common mechanism and is easily exemplified by the bacterial β-lactamases. These enzymes hydrolyze the lactam ring component of various β-lactam antibiotics (e.g. penicillin) to inactivate the drug. A variation on this mechanism is the addition of an acetyl moiety onto the structure of chloramphenicol, thereby rendering it inactive.

Interfering with the accessibility of a target to an antimicrobial. A number of potential mechanisms would fall into this category. Given that the membrane is the primary barrier between the bacterium and its external environment, alteration of the permeability of the membrane would affect the ability of certain lipophilic antimicrobials to enter the cell. This alteration in permeability could be achieved by altering the composition of the lipid bilayer. Another mechanism makes use of specific transporter systems that many bacteria maintain to specifically export antibiotics out of the bacterial cell. A wide variety of these so-called drug efflux pumps have been described for many organisms (e.g. *P. aeruginosa*). It should be noted that other more general efflux systems have been described for some organisms. The *mtr* locus of *N. gonorrhoeae* is such an example.

Production of new enzymes to bypass the targeted site. Some bacteria are able to synthesize new enzymes that can carry out a specific function but that have a significantly decreased affinity for a specific antibiotic.

An interesting mechanism for drug resistance may also be available to those pathogens that are capable of growing

in multicellular, sessile, and encapsulated communities known as biofilms. Evidence indicates that bacteria in the biofilm mode of growth exhibit increased resistance to antimicrobial agents. It is not clear whether the resistance is due to a combination of the various mechanisms described earlier, the fact that the biofilm in enclosed in a matrix of extracellular material, or specific physiological changes occurring within the organisms that elicit as-yet undiscovered resistance mechanisms.

As we have seen in previous sections of this chapter, the facility with which bacteria can exchange genetic information allows for the acquisition of many traits by sometimes-unrelated organisms. Such genetic-transfer mechanisms are also important for the bacteria to acquire antimicrobial resistance.

7 Closing Remarks

As has been briefly outlined above, bacterial pathogenesis involves a large, complex interplay of regulatory networks and virulence factors to allow pathogens to inhabit their hosts and cause disease. This interplay between host and bacteria has resulted in many pathogens becoming specific for certain host species as they evolve to proficiently colonize and invade the host. The transfer of various virulence genes between pathogenic species increases the fitness of pathogen populations and allows them to survive in an increasing number of hosts and specialized niches. Pathogens adapt to changes in their environment by being able to sense changes in their hosts and respond by producing virulence factors that aid in their survival. As one might imagine, these adaptations require an intricate balance of the expression of certain genes. For some of the virulence factors, details regarding the mechanisms and genetics have been elucidated. In many cases, the genetic regulation is poorly understood. While we have made great progress in characterizing the molecular basis of pathogenesis, we cannot define the full complement of factors required for pathogenicity. The advent of new technologies such as DNA microarrays combined with the sequencing of ever-increasing numbers of bacterial genomes is allowing for the comparison of gene complements and genetic expression between organisms. Many common products and motifs have been discovered between pathogenic organisms and these observations are increasing the pace with which the molecular mechanisms of pathogenesis can be and are being deciphered. Nonetheless, studies of the array of products and strategies that bacterial pathogens use to survive within their hosts are always revealing novel and surprising findings that illustrate the complexity that is bacterial pathogenesis.

ISBN: 3-527-30543-2

Photocycle
Reaction sequence initiated by photoisomerization of the retinal of bacteriorhodopsin.

Photointermediates
States of bacteriorhodopsin that arise transiently in the photocycle, identifiable through their distinct spectral properties and from the structure of the protein and the retinal.

Retinal Schiff Base
Covalent bond between the C_{15} atom of the retinal and the side-chain amino nitrogen (NZ) of Lys216, with the nitrogen normally in the protonated state.

Schiff Base Counterion
Complex of ionic side chains and bound water with a net negative charge that compensates the positive charge of the protonated Schiff base.

Transmembrane Helix
An α-helical polypeptide segment that traverses the lipid bilayer, a typical structural motif in membrane proteins.

Ion Pump
Membrane protein that utilizes a chemical or photochemical reaction to drive the energetically uphill translocation of an ion across the membrane.

Chemiosmotic Coupling
General biological principle in which pumps generate a transmembrane proton gradient, and the protons moving down the gradient through specific membrane proteins provide energy for a variety of metabolically useful reactions.

Bacteriorhodopsin is a light-driven pump that generates an electrochemical gradient for protons across the membrane. It is unique among such transporters, widespread in biology, in being a small, seven-transmembrane helical protein. Its remarkably simple transport mechanism is driven by the thermal reisomerization of the photoisomerized 13-*cis* retinal to all-trans. The ease of performing static and time-resolved spectroscopy of many kinds, as well as the propensity of the protein for crystallization, have generated a large amount of valuable information about the transformations of the retinal and the protein during the transport cycle. The data describe how the motions of the retinal cause structural changes that result in proton transfers between donor and acceptor groups inside the protein and in the release and uptake of a proton at the opposite membrane surfaces. As a result, today, bacteriorhodopsin is the best-understood ion pump.

1 Introduction

Bacteriorhodopsin is a small (26 kDa) integral membrane protein, the prototype of seven-helical G-protein-linked receptors. It is found in extended two-dimensional hexagonal arrays in the cytoplasmic membrane of halobacteria, the ''purple membrane'' patches. Upon illumination, this retinal-containing protein transports protons against a transmembrane gradient. Photoisomerization of the retinal from all-trans to 13-cis,15-anti sets off a sequence of thermal reactions, the ''photocycle,'' in which changes of the retinal cause a cycle of structural changes in the protein, and these result in vectorial proton transfers between donor and acceptor groups. Together, the internal transfers add up to full translocation of a proton from the cytoplasmic to the extracellular side of the protein and thus generate a transmembrane electrochemical gradient for protons. This light-driven gradient is utilized for chemiosmotic coupling, in the same way as in other membranes in which it is generated by redox reactions, to the synthesis of ATP, the uptake of K^+ and nutrients (amino acids), and the transport of Na^+ out of the cells.

2 Overall Structure of the Protein

Bacteriorhodopsin forms trimers, which assemble in the two-dimensional hexagonal lattice of the purple membrane. This specialized membrane contains only bacteriorhodopsin and specific lipids (about 10 lipids/protein), and its regular crystalline lattice made it possible to determine the structure of the protein by cryoelectron microscopy of single sheets, ultimately to 3 Å resolution. Three-dimensional crystals can be grown from detergent-solubilized bacteriorhodopsin in cubic lipid phase, and from X-ray diffraction the structure of the protein has been described at increasingly better resolutions, most recently to 1.47 Å. From these crystallographic studies, the protein is known to consist of seven transmembrane helices with short interhelical loops and short N and C termini. Three of the helices, B, C, and D, are normal to the plane of the membrane and four, A, E, F, and G, are inclined at various but small angles to the perpendicular. The single retinal per protein molecule is bound to the ε-amino group of Lys216 forming a protonated Schiff base near the middle of helix G, while its polyene chain lies at a small angle from the membrane plane (Fig. 1).

The Schiff base divides the seven-helical bundle into extracellular and cytoplasmic halves. The trajectory of the transported proton is through the two ''half-channels'' formed by these regions. Identification of the residues and bound water that participate in these half-channels has been the objective of much work in the last few decades. Their locations and how they interact are known from crystallography, infrared spectroscopy, and solid-state nuclear magnetic resonance (NMR). The extracellular half-channel contains numerous polar and hydrogen-bonding residues and a three-dimensional network of tightly bound water. Mutational studies have shown that the polar side chains play roles in the release of protons to the extracellular surface. The anionic Asp85 and Asp212 are hydrogen-bonded to the centrally located water402 that receives a hydrogen bond from the protonated retinal Schiff base. The Asp85/Asp212/water402 complex is the counterion to the charge of the Schiff base, but in the photocycle it is Asp85

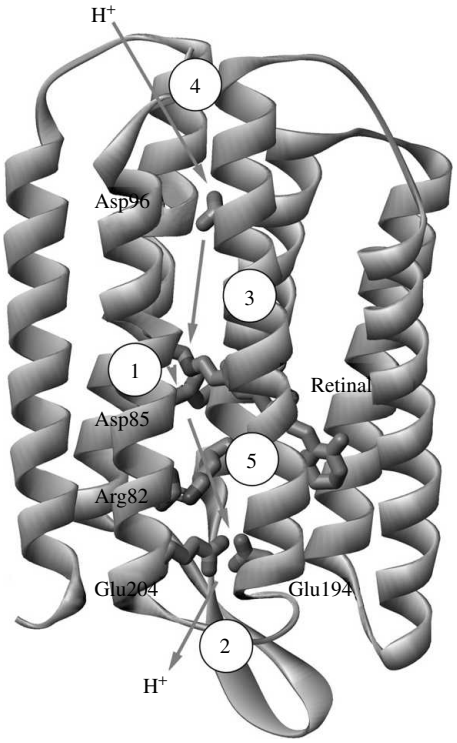

Fig. 1 Three-dimensional structure of bacteriorhodopsin showing the seven transmembrane helices, the retinal, and functionally important residues as marked. The arrows with numbers represent proton transfer events in their sequence. (Reproduced with permission from Luecke et al. (1999) *Science* **286**, 255–260.)

that becomes the acceptor of the Schiff base proton. The pathway for the transported proton is a chain that leads from Asp85 via Arg82, Glu204, and Glu194, with seven intervening water molecules, to the extracellular surface. In contrast, the cytoplasmic half-channel contains hydrophobic residues between the retinal and Asp96, the proton donor in the reprotonation of the Schiff base. The side chain of Thr46 forms a hydrogen bond with the carboxyl group of Asp96, raising its pK_a high enough to keep it protonated. This region is also connected to the retinal, but through a chain of covalent bonds and hydrogen bonds, with the participation of part of helix G that forms a π–bulge near Lys216, two water molecules, and Trp182 that contacts the retinal at the 13-methyl group. The participants of the extracellular and cytoplasmic chains are the candidates for linking the events at the retinal Schiff base first to proton release and then to uptake at the two membrane surfaces.

3 Chromophore and the Photocycle

The chromophore with all-trans, 15-anti retinal has a broad absorption band with a maximum at 568 nm. This is considerably red-shifted from that of retinal (380 nm) or a retinal analogue with a protonated Schiff base (440 nm). The ''opsin shift'' originates from the only partial compensation of the positively charged retinal Schiff base by the counterion complex, and the distortion of the polyene chain of the retinal in its binding site. The all-trans chromophore exists in thermal equilibrium with the 13-cis,15-syn configuration, which absorbs at 555 nm. Sustained illumination converts the retinal to 100% all-trans, 15-anti (''light-adaptation''), and it is the photoreaction of this isomer that is normally active in transport.

The photochemical cycle of the all-trans chromophore is described by the intermediate states J, K, L, M, N, and O and their substates and the sequence of their interconversions (Fig. 2). Each intermediate is characterized by a distinct absorption maximum in the visible and numerous vibrational bands from the retinal in the infrared and Raman, as well as from the

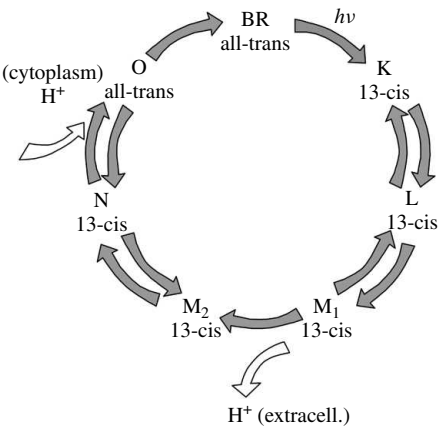

Fig. 2 Photocycle scheme for bacteriorhodopsin. The intermediate states, described in the text, are shown with the isomeric state of the retinal indicated. In all states other than BR and O, the retinal is 13-cis. Proton release is to the extracellular side of the membrane; uptake is from the cytoplasmic side.

protein in the infrared. They correspond to stages of the progress of the photocycle.

3.1 The K State

In the K intermediate that arises on the picosecond timescale, the retinal assumes a twisted 13-cis,15-anti configuration, as indicated by the observation of high-amplitude hydrogen out-of-plane bands, and confirmed by the X-ray diffraction structure of the retinal. The latter had shown that the bond angle at C_{13} is anomalously wide, attributable to the fact that the retinal binding site resists deformation on the timescale in K. This keeps the retinal linearly extended in spite of rotation of the $C_{13}{=}C_{14}$ bond that would otherwise result in a bent polyene chain. Counterrotations of the $C_{14}{-}C_{15}$ and $C_{15}{=}N$ bonds ensure that the direction of the N−H bond remains roughly in the extracellular direction. However, the N−H−O angle that the Schiff base forms with water 402 is now more sharply angled, making its hydrogen bond weaker. This is in accordance with an anomalously low Schiff base band frequency and loss of its deuterium isotope effect, as well as a shift of the O−H stretch bands of a water molecule (assigned to be water 402) to higher frequencies.

3.2 The L State

K converts in about 1 μs into the L state that absorbs at about 540 nm. Fourier-transform infrared (FTIR) spectra indicate that in L, changes begin to appear in the protein also, in both extracellular and cytoplasmic regions. The Schiff base band increases in frequency and regains its deuterium isotope effect, indicating that it forms a stronger hydrogen bond than in K. The X-ray diffraction structure of L indicates that this is because rotations of the $C_{13}{=}C_{14}$ and $C_{15}{=}N$ bonds return the N−H−O geometry toward its initial angle. This means that further relaxation of the retinal by proton transfer from the Schiff base to water 402 and thence to Asp85 is made possible.

3.3 The M States and Proton Release to the Extracellular Side

The M states, with deprotonated Schiff base, have strongly blue-shifted absorption

maximum, near 410 nm. The kinetics of this conversion, on a timescale of tens of microseconds as measured in the visible and the infrared, is multiphasic. Analysis of the kinetics suggests that L is in equilibrium with an early M state, M_1, and the mixture of L and M_1 decays together to form M_2 and then the late M state, M_2' (Fig. 2). At pH > 6, the latter occurs in a unidirectional reaction, and thus L disappears as M_2' is formed. The reason for this appears to be that at the higher pH, a proton dissociates from a site in the extracellular region that interacts with Asp85. The proton is then released to the extracellular surface. The site is likely to consist of bound water, and its function depends on Arg82 and the carboxyl groups of Glu194 and Glu204.

The anomalous titration properties of Asp85 reveal how proton release is coupled to protonation of Asp85. The appearance of two apparent pK_as for Asp85 could be modeled by interaction between the proton affinities of the aspartate and the proton release site. They interact in such a way that either may be protonated but not both. This seems to occur also during the photocycle. When Asp85 becomes protonated by the Schiff base, the pK_a of the proton release group is lowered and it dissociates. When the proton is released to the bulk at a pH higher than the pK_a of the proton release site, the pK_a of Asp85 is in turn driven higher, and the deprotonation of the Schiff base becomes complete. The identity of the proton release is still uncertain. Although Arg82, Glu194, and Glu204 are all involved, the released proton is most probably a proton delocalized in the water network rather than one that originates from these amino acid residues.

Solid-state NMR spectra show that at this time a guanidinium group becomes strongly asymmetrical, suggesting relocation of the side chain of an arginine, very probably Arg82. In the crystallographic structures of the M_2 and M_2' states, the side chain of Arg82 moves away from the region of the now-protonated Asp85 and approaches the region of Glu194/Glu204. This shuttling of Arg82 is therefore the means by which Asp85 interacts with the proton release site and the direct cause of the release of the proton to the surface in M_2'. In M_1, the Schiff base remains initially more or less in the same position as before its reprotonation, but in the M_1 to M_2 reaction it rotates to face the cytoplasmic side. Thus, after deprotonation of the Schiff base there is a drastic change in the geometry of the retinal. Before deprotonation, it faces in the extracellular direction, toward water 402 and Asp85, its proton acceptor, but after its deprotonation it turns to the cytoplasmic direction, toward its eventual proton donor, Asp96. This ''reorientation switch'' as well as the modulation of the pK_a of Asp85 prevent reprotonation of the Schiff base by reversal of its deprotonation and confer directionality on the pump.

In the X-ray diffraction structures of the intermediate states, the retinal continues to relax as it passes through the M states, and in M_2' it reaches the configuration bent at C_{13}, as expected for the 13-cis isomer. This thrusts the 13-methyl group against the indole ring of Trp182, which moves toward the cytoplasmic side. The movement of Trp182 and rearrangements of the side chains between helices F and G initiate the outward tilt of helix F and an ''opening'' of the cytoplasmic region. As a result, in M_2, a cluster of three water molecules accumulates near Asp96. One of these, water 504, separates the otherwise hydrogen-bonded Asp96 and Thr46. Another, water 503, connects water 504 with water 502, located near, although

not within hydrogen-bonding distance, the Schiff base. The water cluster in M_2 may be expected to (1) lower the pK_a of Asp96 so as to make it a proton donor and (2) constitute the beginnings of a hydrogen-bonded chain that would, in the next photocycle step, conduct the proton to the Schiff base.

3.4 The N State and Proton Uptake from the Cytoplasmic Side

Reprotonation of the Schiff base by Asp96 produces the N intermediate, which absorbs near 560 nm but with a lower extinction than the initial BR state, as expected for its 13-*cis* retinal. A large-scale protein conformation change in N is evident from electron diffraction, measured either at various times after flash illumination and freezing or at an ambient temperature in a photostationary state of a mutant with long N lifetime. The extensive displacement of the cytoplasmic end of helices F and G in N is confirmed by distance measurements with pairs of spin labels, and with maps of Hg attached to engineered cysteines. The changed accessibilities of spin labels to aqueous quenching agents, and engineered cysteine residues to hydrophilic reagents, further define the conformational changes of the helices and the interhelical loops.

The effects of osmotic agents, hydrostatic pressure, and humidity on the $M_2' \rightarrow$ N reaction and on the protein conformation change, and kinetic analysis of the in-plane cooperativity in the purple membrane lattice, suggest that the rationale of the helical tilt is to increase the hydration of the cytoplasmic region and thereby decrease the pK_a of Asp96. Although widely assumed, the hydrogen-bonded chain of water molecules between Asp96 and the Schiff base has not been directly observed. The conformation with such a chain of water might be a transient state that leads to N, one that does not accumulate in measurable quantities. Recovery of the tilt of helix F is during decay of the N state to the O intermediate, as it is absent in the crystal structure of a mutant that should have an O-like structure. Recovery of the initial state of the cytoplasmic region will reestablish the initial high pK_a of Asp96, and it will have been reprotonated from the cytoplasmic surface.

3.5 The O State

Reisomerization of the retinal to all-trans is made possible by the lowered barrier to bond rotations in the polyene chain upon protonation of the Schiff base. It occurs in the N to O transition, coupled to the reprotonation of Asp96. Residues that contact the chain near the 9-methyl and 13-methyl groups, such as Trp182 and Leu93, facilitate the reisomerization, through steric interaction, that transmits displacements of the protein to the retinal and *vice versa*. The O state has a strongly red-shifted maximum in the visible, at least partly because Asp85 is still protonated, and thus the main component of the counterion to the protonated Schiff base is lacking. Large-amplitude hydrogen out-of-plane vibrations indicate that, as in the K state, the retinal chain is twisted. These features disappear in the final O $\rightarrow$ BR reaction, which appears to be limited by the rate of proton transfer from Asp85 to the still unprotonated proton release site. As expected from the recovery of the low initial pK_a of Asp85, this reaction is unidirectional under all conditions and ensures not only the full repopulation of the initial state but also the

functioning of the proton pump against large transmembrane proton gradients.

4 Properties of Single-site Mutants

Of the 248 amino acid residues in bacteriorhodopsin, only a handful plays an important role in the transport. Their replacement with less functional (e.g. nonprotonable, wrong polarity, or size-mismatched) residues will produce a less effective pump, but only at a saturating light intensity, through increasing the overall turnover time. Only one mutation, that of Lys216, has been reported to eliminate transport altogether by eliminating the covalent binding of retinal. However, even such mutants show transport if reconstituted with a retinal analogue in which the Schiff base is protonated.

The important roles played by Asp85 and Asp96 in bacteriorhodopsin are illustrated, nevertheless, by the altered phenotypes of recombinant proteins in which they are replaced by nonprotonatable residues like asparagine.

When Asp85 is replaced, the purple chromophore becomes blue, similar to the color produced upon protonation of this anionic residue at low pH (<3). The pK_a of the retinal Schiff base is shifted from >13 in the wild type to about 8. The mutation removes the negative charge of Asp85 that is the primary counterion to the positively charged Schiff base and thus the origin of the stability of the protonated Schiff base. The mutation also removes the proton acceptor, and the photocycle of this mutant produces only small amounts of the M intermediate, through loss of the Schiff base proton in the cytoplasmic direction. The D85N mutant shows proton transport at a pH at which the Schiff base is unprotonated, through a series of photocycle steps that occur out of their normal sequence.

Replacement of Asp96 with asparagine greatly stabilizes the M intermediate, as the internal proton donor to the Schiff base is removed. The Schiff base is now reprotonated directly from the cytoplasmic surface, and its rate becomes slow and pH dependent. Mutation of many residues at the cytoplasmic surface near Asp96 does not hinder reprotonation of the Schiff base, but it decouples the reisomerization of the retinal to all-trans from reprotonation of Asp96. In these mutants, the lifetime of N becomes very slow and pH independent.

Replacement of residues implicated in proton release, Arg82, Glu194, and Glu204, with glutamine eliminates proton release during the rise of the M state. Instead, the proton is released to the extracellular surface in the last step of the photocycle, the O to BR reaction. Most likely, with the proton release site rendered nonfunctional, this proton is directly from Asp85 that deprotonates in the last photocycle step in any case.

5 Pump Modes, Energetics

The release and uptake of protons at the extracellular and cytoplasmic surfaces respectively, brought about by the intraprotein proton transfer reactions of the photocycle, can be measured by absorption changes of pH indicator dyes either in the bulk or covalently linked to a surface residue. The pump functions well both at pH > 6, at which proton release to the extracellular surface precedes proton uptake from the cytoplasmic side, and at pH < 6 (the pK_a for proton release), at which the

sequence is reversed. The light-driven proton pump is highly effective: the quantum yield for producing the K intermediate is about 0.6, and the protons transported is close to one/photocycle. From calorimetry, it appears that nearly 50% of the energy gain in the K intermediate is conserved in the form of a transmembrane electrochemical difference for protons. On the other hand, feedback mechanisms, so far not well defined, appear to limit the pump at very high proton gradients, perhaps by shunt reactions.

6
A Family of Retinal Proteins

Bacteriorhodopsin is one of three kinds of similar retinal proteins in halobacterial membranes. Their functions are all based on the photoisomerization of all-trans retinal to 13-cis,15-anti and the protein reactions that accompany its thermal reisomerization. Halorhodopsin is an inward-directed light-driven chloride ion pump. It lacks homologues for Asp85 and Asp96 (containing threonine and alanine at these locations respectively), and the retinal Schiff base does not deprotonate during the photocycle. Sensory rhodopsins I and II are receptors for phototactic behavior. A profound similarity in the mechanisms of these proteins with different functions is indicated by the fact that, for the most part, their activities are interconvertible with minimal perturbations. Thus, the D85T mutant of bacteriorhodopsin binds chloride, exhibits a photocycle similar to that of halorhodopsin, and transports chloride from the extracellular to the cytoplasmic direction. Halorhodopsin, in turn, transports protons when the weak acid, azide, is added. The azide binds near the Schiff base and functions as a proton acceptor like Asp85 in bacteriorhodopsin, and another azide molecule is the proton donor on the cytoplasmic side, as in the D96N mutant of bacteriorhodopsin. Sensory rhodopsin I transports protons such as bacteriorhodopsin when the transducing protein that is normally tightly bound to it is genetically deleted.

Keywords

Quantitative Trait Loci
Loci that contribute to the variance of a continuously distributed characteristic.

Concordance
The proportion of a sample of pairs of relatives (e.g. twins) who both show a particular trait or disease. The most useful way of calculating concordance is ''probandwise,'' that is, a series of twins is ascertained via affected index cases or probands. The probandwise concordance is then simply the number of affected cotwins divided by the total number of cotwins.

Relative Risk
Strictly, relative risk is the proportion of individuals exposed to a risk factor for a disorder who are affected divided by the proportion of nonexposed individuals who are affected. In genetic studies, the term is sometimes used slightly more loosely to refer to the proportion of relatives of affected individuals of a particular type (e.g. siblings) who are affected, divided by the proportion of the general population who are affected.

Etiology
The causes of a particular disorder.

Variable Number Tandem Repeat (VNTR)
A small motif of DNA that is repeated tandemly a varying number of times to produce alleles of different sizes.

Single Nucleotide Polymorphism (SNP)
A nucleotide substitution occurring within DNA.

Proband
An individual identified as having a characteristic or disorder of interest through whom other family members are ascertained.

Phenotype
An observable characteristic of an individual.

Behavior genetics is the study of the inheritance of normal psychological traits, such as personality and cognitive ability, as well as abnormal traits and illnesses, such as mood disorders and psychoses. The questions addressed by behavior genetics include the following: Why do individuals differ? Why aren't children of the same parents alike? To what extent are genes and environmental factors accountable for the differences and similarities in human behavioral traits? What are the salient

genes and environmental factors? How do these genes and environmental factors act, coact, and interact to produce the phenotype? To what extent is the covariation of phenotypes the result of the same genes and environmental factors acting on both? Does the extent to which genes affect a phenotype change over the life span and are different genes important at different stages of development? Behavioral traits and disorders, with some rare exceptions, show complex patterns of inheritance involving gene–environment interplay and therefore quantitative genetic methods assume a particularly important role alongside molecular techniques.

1 Complex Phenotypes

Behavioral and psychiatric phenotypes usually exhibit complex, or multifactorial, inheritance, resulting from a combination of multiple genes and environmental contributors, and most normal behavioral traits are continuously distributed in the population. For readers used to dealing with classic Mendelian traits, these features may at first be puzzling. However, if we start by considering a single gene with two alternative forms or alleles, *A* and *a*, as we see in Fig. 1, we have three genotypes *aa, Aa,* and *AA*, whose phenotypic values on some particular scale are x_1, x_2, and x_3 respectively. Depending on the value of x_2, we can have three possible situations. When x_2 is equal to x_3, we have classical dominance of *A* with respect to *a*, whereas if x_2 is equal to x_1, we have recessivity.

If the value of x_2 is exactly midway between x_1 and x_3, we have a purely additive gene effect. Suppose the two alleles have frequencies in the population of p and q (equal to $1 - p$) and assuming there is no migration, mutation, or selection against a genotype, the genotype would be distributed in the population as follows:

$$\text{Genotypes: } aa \; Aa \; AA$$

$$\text{Frequency: } p^2 \; 2pq \; q^2$$

that is, in *Hardy–Weinberg equilibrium*. If, for the sake of simplicity, we take $p = q = 0.5$, and suppose that we have variations about the mean value in each genotype due to environmental factors, we might see three phenotypic distributions as in Fig. 2(a), occurring in the proportions 1 : 2 : 1. For a trait controlled by two loci with each having two alleles of equal frequency and additive effect, we would see, as in Fig. 2(b), five phenotypic distributions occurring in the proportions 1 : 4 : 6 : 4 : 1. In general then, the relative proportions of phenotypes controlled by N loci will be given by $(p + q)^{2^N}$. As the size of N increases, the overall phenotypic distribution more closely approximates a normal distribution, which is the limiting case when N becomes very large. It is thought that most continuously

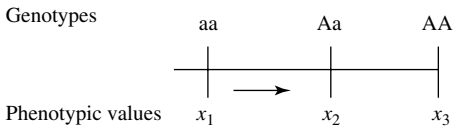

Fig. 1 Genotypes and corresponding phenotypic values.

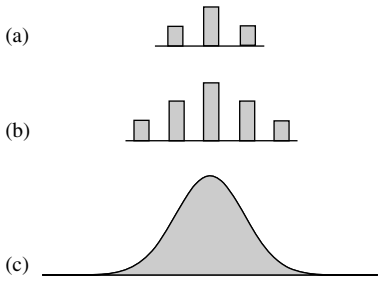

Fig. 2 Distribution of traits influenced by additive genetic effects. (a) A single biallelic gene gives rise to three phenotypes; (b) two biallelic genes give rise to five different phenotypes; (c) numerous additive genetic and environmental factors give rise to continuously distributed phenotypes.

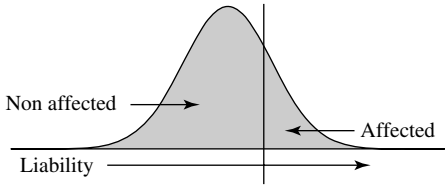

Fig. 3 A liability threshold model in which it is assumed that multiple genes and environmental factors contribute to the underlying liability to a produce a normally distributed liability towards a disorder. A person who falls below the predefined threshold is not affected by the disorder whilst all those who fall above the threshold are affected.

distributed hereditary traits are due to *polygenic* mechanisms of this kind, with each individual gene still being transmitted according to Mendel's laws. The multiple genes that contribute to the continuous variation of a multifactorial phenotype are referred to as quantitative trait loci (QTL).

Some behavioral traits such as psychiatric disorders display discontinuous characteristics, for example, when an individual is categorized as unaffected or affected by schizophrenia, or depression. Although some comparatively rare disorders such as Huntington's disease and early-onset varieties of familial Alzheimer's disease show Mendelian segregation, most psychiatric disorders do not conform to Mendelian patterns of inheritance. For such phenotypes, we can consider that there is an underlying continuum of liability to the disorder. It is usually assumed that liability has an approximately normal distribution resulting from the combined effects of multiple QTLs and environmental effects. Individuals who fall below a predefined threshold are unaffected whilst those who at some point exceed it are affected. This is referred to as the liability threshold model (see Fig. 3).

2 Quantitative Genetics

Phenotypic variance results from both genetic and environmental influences, and one of the concerns of quantitative genetics is the partitioning of the phenotypic variance into its environmental and genetic components. This is discussed in more detail in Sect. 2.4. The phenotypic covariance between family members results from both their shared genes and shared environments. By taking advantage of the different genetic and environmental relationships between family members, we are able to quantify the extent to which genes and environment influence a phenotype. To do this, we employ family, twin, and adoption studies.

2.1 Family Studies

Family studies are used to establish the extent to which behavioral phenotypes cluster in families. For example, a familial influence would result in relatives correlating positively for a continuous trait or, when studying a disorder, relatives of probands (individuals affected by the disorder, also referred to as an index case) having a higher prevalence than the relatives of controls (individuals unaffected by a disorder, often matched to the proband for characteristics such as age, sex, and ethnicity). We can also compare correlations and concordances between family members with differing degrees of genetic relatedness to the proband. The main sources of genetic correlation or covariance between relatives are called additive variance and dominance variance. Essentially, additive variance reflects the extent to which the QTLs contributing to a trait show simple additive effects and dominance variance reflects the extent to which heterozygotes deviate from the mid values between homozygotes (Fig. 1). The genetic covariance between pairs of relatives is given by the simple expression $\beta V_A + \alpha V_D$, where β is the (average) proportion of genes held in common, α is the probability that at any given locus the pair of relatives share two alleles that are identical by descent (IBD) from common ancestors, V_A is the additive genetic variance, and V_D is the nonadditive genetic, or dominance variance. In addition to genetic covariance, family members share the home environment in which they are raised and this contributes a proportion of variance V_C. The sources of covariance between different family members can be seen in Table 1.

One of the major limitations associated with family studies is the inability to distinguish between genetic and environmental effects. So-called competition effects between family members may reduce resemblance between relatives and make a trait appear less genetically influenced than it actually is. More commonly shared environment contributes positively to resemblance between family members and therefore familial clustering of a phenotype is not sufficient evidence of genetic causation.

2.2 Twin Studies

Identical, or monozygotic (MZ) twins are the product of a single fertilized egg

Tab. 1 The sources of covariance between pairs of relatives.

Relationship to proband	*Genetic relationship*	*Phenotypic covariance*
MZ twins	$V_A + V_D$	$V_A + V_D + V_C$
DZ twins	$0.5V_A + 0.25V_D$	$0.5V_A + 0.25V_D + V_C$
Full sibs	$0.5V_A + 0.25V_D$	$0.5V_A + 0.25V_D + V_C$
Parent or offspring	$0.5V_A$	$0.5V_A$
Half sibs raised together	$0.25V_A$	$0.25V_A + V_C$
Raised apart		$0.25V_A$
Uncles/aunts/nephews/nieces	$0.25V_A$	$0.25V_A$
Cousins	$0.125V_A$	$0.125V_A$
Grandparents	$0.25V_A$	$0.25V_A$

and consequently are genetically identical. Fraternal or dizygotic (DZ) twins, on the other hand, result from two separate fertilized eggs and so share on average only 50% of their genes, the same as full siblings. Hence, if genes contribute toward predisposition for a phenotype, MZ twins will tend to be more similar than DZ twins. If MZ twin pair correlations or concordances significantly exceed those observed for DZ twins, we can conclude a genetic influence for the phenotype, with environmental variables accounting for all the difference between MZ twins. As full sibs share, on average, the same number of genes as DZ twins, it would theoretically be possible to substitute them into such analyses. However, DZ twins are a better comparison since they are the same age and are likely to have shared more similar environments and major life events. One of the requirements of twin studies is that correct determination of zygosity is essential, and misclassification can result in meaningless results. For example, if genetic effects are present and MZ pairs are incorrectly assigned as DZ, the DZ correlations will be artificially inflated, decreasing the difference between MZ and DZ correlations and resulting in an underestimate of heritability, and an overestimate of the common environment effect. In practice, zygosity assignment is frequently based on questionnaires. These typically ask such questions as whether the twins are often mistaken one for the other by friends or if they are as alike as ''two peas in a pod.'' While genotyping at several highly polymorphic DNA markers is a more accurate method of zygosity testing, it is also far more costly and may be uneconomical for very large studies where the approximately 95% accuracy of questionnaires may be acceptable.

A potential limitation is that twins have atypical obstetric and perinatal histories and suffer from birth complications and low birth weight more frequently than nontwins do, and consequently, conclusions drawn from twin studies may not be generalizable to nontwins. For example, on average, the early cognitive ability of twins is slightly lower than that of singletons and twins probably have a slightly elevated risk of mental retardation. However, in practice, the long-term impact of this for most behaviors is limited, and by approximately five years of age, biological, behavioral, and emotional differences between twins and nontwins would have diminished.

The classic twin approach depends on the ''equal environments assumption'', that is, MZ twins share their environments to roughly the same extent as DZ twins. However, some studies suggest that MZ twins may share more similar postnatal environments, such as having more friends in common, and they may also be perceived and treated more similarly than DZ twins. The extent to which this may invalidate the results of twin studies has been tested in a number of ways. One approach is to attempt to measure aspects of environmental sharing and examine whether they are associated with the trait being studied. For example, a study of depressive disorder in adult same-sex twins found that MZ twins had on average shared a bedroom for longer as children and were in more frequent contact as adults than DZ twins, but these indicators of environmental sharing did not predict concordance for depression. Another approach is to look at the effects of mistaken zygosity on parental treatment of their twins. Up to 20% of parents think that their MZ twins are DZ or vice versa. The prediction might be that MZ twins thought to be DZ by their parents would be treated less similarly than MZ

twins where the parents were correct in their assumption about zygosity. DZ twins thought to be MZ would be treated more similarly than correctly assigned DZ twins. In fact, studies of traits such as personality, intelligence quotient (IQ), and depression symptoms in childhood have found that parental misclassification has negligible effect on twin resemblance. Finally, studies of MZ twins who have been reared apart make it possible to eliminate the effects of shared environment altogether, and comparisons of the MZ twins reared together with those reared apart for traits such as personality reveal that correlations are similar for both types. Thus, even if MZ twins do share a greater environment than DZ twin pairs, it does not significantly influence their similarity for behavioral phenotypes. Therefore, the available evidence suggests that the equal environment assumption is a reasonable conjecture. The potential effects of prenatal environment also need to be considered in twin studies as MZ twins often share a chorion, whereas DZ twins never do. This may also influence MZ twin similarity, although there is little evidence to support this.

Twin studies also assume random mating of the parents, in which proband parents do not correlate more for the observed phenotype than would be expected by chance. However, assortative mating where the parents correlate highly for the trait has been detected for some phenotypes, such as IQ and antisocial behavior. This may increase the proportion of predisposing genes shared by DZ twins above the expected 50%; thus DZ twins would be phenotypically more similar than if random mating was occurring. There is no effect on the genetic relatedness between MZ twins as they already share 100% of their genes. Consequently, the difference between MZ and DZ twin correlations will be reduced, resulting in underestimation of the heritability.

Despite their limitations, twin studies remain the most used tool in disentangling the genetic and environmental influences on behavior. Figure 4 summarizes twin study results for a number of disorders and traits. There are clear MZ–DZ differences for some phenotypes such as schizophrenia, manic depressive disorder, unipolar depression, and cognitive ability as measured by IQ tests, suggesting genetic effects. In the case of bulimic behavior and childhood conduct disorder, there is evidence of familiality (there are positive correlations) but little suggestion of genetic effects (modest differences in the MZ and DZ correlations).

However, the classic twin study is not the end of the story. There are a number of possible directions in which twin studies can be elaborated upon. Extending twin studies to include other family members is one useful method that has already been applied and which has potential for future research. Furthermore, the offspring of MZ twin pairs are of particular interest. The son of an MZ father shares 50% of his genes with both his father and his uncle, thus comparison of the correlation between uncles and nephews with the father and son pairs may inform us more about the genetic basis of the phenotype, whilst eliminating any confounding effects of common environment or G × E correlation. Similarly, we could compare both sets of offspring from such a family set-up as these are genetically similar to half sibs. See Fig. 5.

2.3 Adoption Studies

The effects of genes and environment on development of behavioral traits can also

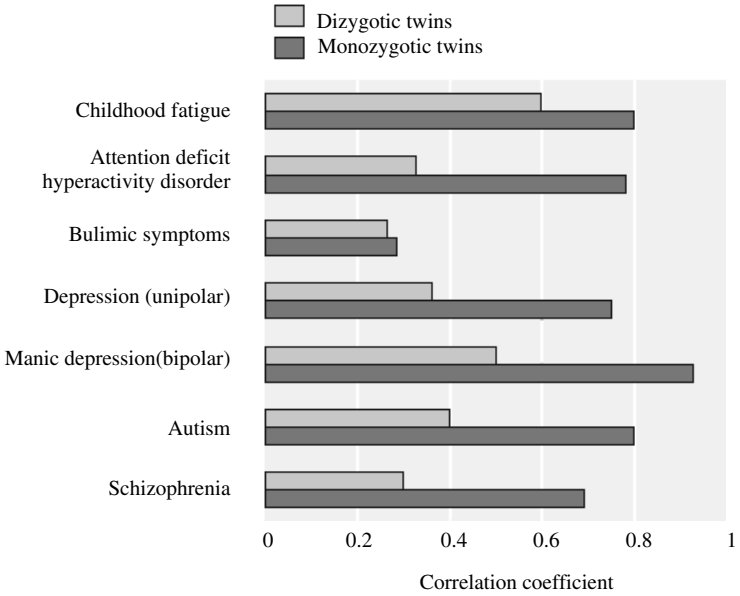

Fig. 4 Monozygotic and dizygotic twin correlations for various disorders. (Taken from McGuffin, P., Martin, N. (1999) Science, medicine, and the future. Behaviour and genes, *BMJ* **319**, 37–40.)

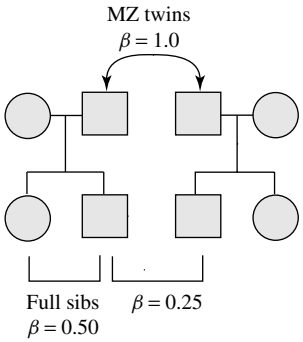

Fig. 5 The genetic relationships (β) between the offspring of monozygotic twins.

be differentiated using adoption studies, although for practical reasons, these have been used less extensively than twin studies. There are three main variations on the adoption design. Firstly, the adoptee study design compares the frequency of a disorder or trait in the adopted-away offspring of parents who have the trait and adopted-away offspring of parents who do not. A second type is the adoptee's family study. This involves taking affected adoptees as the index cases. The prevalence of the trait in biological relatives can be compared with that in adoptive relatives or to that in the relatives of control adoptees. A higher rate of disorder in those biologically related to the index cases indicates a genetic effect. One can also compare the prevalence of the disorder in the biological parents of adopted-away probands with that in the

biological parents of nonadoptees as a test of whether the environment or rearing has any effect. A third approach is the cross-fostering study, which compares the rates of disorder in adoptees with no biological risk but raised by an affected adoptive parent with the disorder in adoptees with biological but not environmental risk. This is the most complicated and practically difficult design but it allows the possibility of testing for the effects of genes, environment of rearing, and the combination of the two. An example was a study of antisocial behavior by Mednick and colleagues who found an increased risk of having a criminal record in male adoptees with either a criminal adoptive father or a criminal biological father but an even higher rate in those who had both a biological and an adoptive father who had a criminal record. However, the disorder where adoption designs have been used most extensively is schizophrenia. Some of the main results from schizophrenia adoption studies are summarized in Table 2. They show a consistent pattern favoring a genetic contribution but in contrast with the study of antisocial behavior just mentioned, there is little evidence of a family environmental effect.

A general criticism of adoption studies is that adoptees may not be representative of the population as a whole. For example, the circumstances surrounding adoption may be particularly stressful placing adoptees at increased risk of behavioral and psychiatric disorders. Parents who give up their children for adoption may do so because of illness and therefore will tend to have increased levels of psychopathology. Finally, adoptive parents are likely to be unrepresentative in the opposite direction as adoption agencies will tend to screen out many "negative" attributes such as preexisting psychopathology when placing a child.

A related complication with adoption studies is selective placement. Some agencies attempt to place adoptees with families that resemble their biological parents in terms of social or ethnic background. This could result in genetic relatives, who have been independently adopted, sharing a correlated environment. For example, a tendency toward selective placement has been suggested in some studies of IQ, although there is little evidence for selective placement in many other traits. Another fundamental limitation of adoption studies is that adoption is becoming rarer as a result of increasing contraception and abortion, along with the removal of the stigma of being a single parent.

2.4 Partitioning of the Phenotypic Variance

As described above, observed phenotype (V_P) can be partitioned into genetic (V_G) and environmental (V_E) components, such that:

$$V_P = V_G + V_E \quad (1)$$

Furthermore, the genetic variance can be partitioned into additive genetic effects (V_A) and dominance deviation effects (V_D) that result from interactions of the alleles found at a single locus. We may also encounter epistasis, the interaction or multiplicative effect of genes at different loci. In practice, this is not easy to distinguish from dominance in human studies. However, one example of a disorder where the pattern of inheritance would be in keeping with epistasis is schizophrenia, where the concordance rate (i.e. the proportion) of relatives and of index cases who are also affected is around

Tab. 2 Examples of adoption studies of schizophrenia, not age-corrected. (Taken from McGuffin, P., Owen, M. J., O'Donovan, M. C., Thapar, A., Gottesman, I. I. (1994) *Seminars in Psychiatric Genetics*, Gaskell, London.)

Study	*Type of study*	*Diagnosis*	*Genetic relatives of a schizophrenic*	*Not genetically related to schizophrenic*
Heston (1966)	Adoptee	Schizophrenia	10.6% of 47 adoptees who had a schizophrenic mother	0% of 50 control adoptees
Rosenthal et al. (1968)	Adoptee	Schizophrenia spectrum disorder	18.8% of 69 children of schizophrenics raised by normals	10.1% of 79 control adoptees
Wender et al. (1974)	Cross-fostering	Schizophrenia spectrum disorder	18.8% of 69 children raised by normals	10.7% of 28 children of controls raised by future schizophrenics
Kety (1983) Kety et al. (1994)	Adoptee's family: national sample (47 chronic schizophrenic adoptees)	Chronic and latent (DSM-II) schizophrenics	15.8% of 279 biological relatives of adopted-away schizophrenics	18% of 228 adoptive relatives of schizophrenics and relatives of control adoptees
Kendler et al. (1984, 1994)	Reassessment of Kety's data (31 adoptees with spectrum disorder)	DSM-III schizophrenia, schizotypal personality disorder, RDC schizoaffective disorder, mainly schizophrenic	14.4% of 209 biological relatives of adopted-away schizophrenics (23.5% in first-degree relatives, 9.9% in second-degree relatives)	3% of 299 adoptive relatives of schizophrenics and relatives of control adoptees
Tienari (2000)	Adoptee	Schizophrenic/paranoid psychosis	6.7% of 164 adoptees who had schizophrenic biological parents	2.0% of 197 control adoptees

50% for MZ twins, 10 to 12% for DZ twins or full siblings, but only 2 to 3% for second-degree relatives such as uncles/aunts or grandparents. One explanation of why concordance declines more steeply than the proportion of shared genes (see Fig. 6) would be an interactive effect of multiple loci. For example, Risch has suggested on mathematical grounds that just two or three loci with epistatic effects would be sufficient to explain the inheritance of schizophrenia. However, recent molecular studies appear to indicate that a larger number of loci is involved.

As we also discussed earlier, part of the environmental variance is common or shared environment (V_C), which is defined as any environment that is common to a pair of relatives and makes them more similar. In contrast, individual-specific, or nonshared environmental variance results from any environmental effects that produce differences between relatives (V_E).

Phenotypic variance may also be affected by gene–environment interaction and gene–environment correlation. Gene–environment interaction occurs when specific genotypes confer susceptibility to specific environments. For instance, it has been demonstrated that adoptees who faced adversity during their upbringing were at increased risk for criminality if at least one biological parent had antisocial behavior. More recently, Caspi and his colleagues found more specific evidence of gene–environment interaction. Young men who had experienced early parental maltreatment had an increased risk of antisocial behavior if they had inherited the X chromosomal gene that results in low activity of an enzyme involved in brain signaling, monoamine oxidase A (MAOA). Men who had the alternative, high-activity form of the MAOA gene and early maltreatment showed no significant increase in antisocial behavior when compared with men who had not been maltreated. Gene–environment correlation may result from the covariation genotype and environmental factors. Three types of gene–environment (G-E) correlation have been described: passive, active, and evocative. Passive G-E correlation arises because children inherit both genetic risk factors and environment factors from their parents. For example, a musically talented parent could transmit both predisposing genes and a predisposing environment to their offspring. Active correlation occurs because people search out or modify environments to suit their genetic predisposition. An example of this would be a person of high musical ability seeking out environments where they could make best use of their talents.

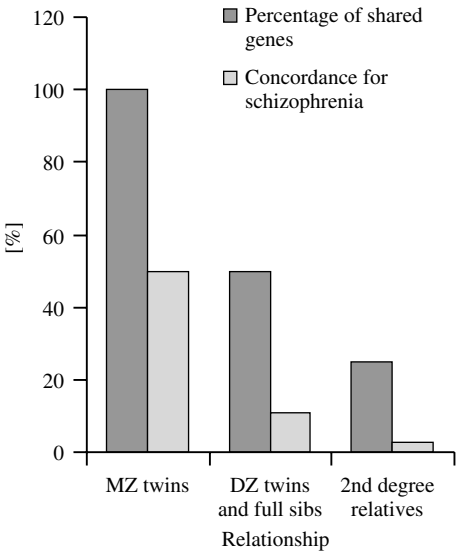

Fig. 6 The genetic concordances between family members and corresponding concordances for schizophrenia. The concordances decline more steeply than the percentage of shared genes.

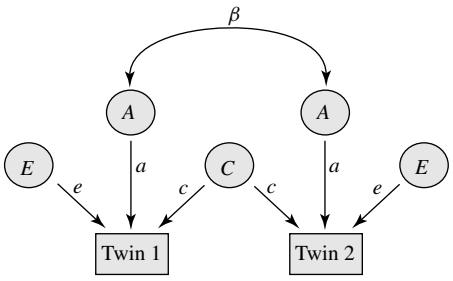

Fig. 7 An ACE path diagram. Path analysis can be used to estimate the contribution of the path coefficients *a*, *c*, and *e*, to the covariance or correlation between twin pairs. β, genetic correlation between twin pairs, 1.0 for monozygotic twin pairs and 0.5 for dizygotic twin pairs; *a*, path coefficient for additive genetic effects; *c*, path coefficient for common environmental effects; *e*, path coefficient for nonshared environmental effects; *A*, additive genetic variance; *C*, common environment variance; *E*, nonshared environment variance.

Finally, evocative correlation results from others' reactions to a person based at least partially on that person's genotype. For example, a musically gifted child's abilities may be recognized by her teachers and parents, who ensure that she has the tuition and equipment to fulfil her promise.

Therefore, the phenotypic variance is the consequence of additive genetic variance, nonadditive genetic variance, common environmental variance, and nonshared environmental variance, as well as the effect of gene–environment interactions and correlations. This can be expressed in Eq. (2):

$$V_P = V_A + V_D + V_C + V_E + V_{G\times E} + 2\mathrm{Cov}_{GE} \quad (2)$$

where $V_{G\times E}$ is the variance due to gene–environment interaction and $2\mathrm{Cov}_{GE}$ is the covariance due to gene–environment correlation.

Although genetic and environmental variance cannot be directly measured or observed, it may be possible to estimate them indirectly from the observed phenotypic variances and covariances.

The extent to which genes are accountable for the phenotypic variance in the population, or the proportion of variance in the liability for a phenotype is referred to as the heritability. Strict sense or narrow heritability refers only to the additive genetic effects whereas broad heritability (or degree of genetic determination) is the proportion of the phenotypic variance accounted for by total genetic variance V_G, including both additive and nonadditive effects.

$$\text{Broad heritability} = \frac{V_G}{V_P} \quad (3)$$

$$\text{Narrow heritability} = \frac{V_A}{V_P} \quad (4)$$

Similarly, it may be of interest to estimate the extent to which the variance of a phenotype is influenced by shared environment, V_C/V_P, and by environment that is not shared, V_E/V_P. A useful methodology for such tasks is provided by path analysis.

2.5 Path Analysis

Figure 7 illustrates a simple path model for a trait where it is assumed that the variance can be explained by additive genetic effects (A), shared environmental effects (C), and nonshared environment (E). The observed correlation between a series of twins (twin 1 and twin 2) can be calculated for the trait under investigation. The expected value of the correlation between the twins in terms of path coefficients can be obtained by tracing the connecting paths, providing the equation:

$$r(\text{Twin 1})(\text{Twin 2}) = (a\times\beta\times a) + (c\times c) = \beta a^2 + c^2 \quad (5)$$

where the correlation between genotypes $\beta = 1.0$ for MZ twins and 0.5 for DZ twins.

Therefore, if we calculate the correlations based on observed measures for MZ and DZ twins, rMZ and rDZ, we have a set of simultaneous equations that can be easily solved for a^2 and c^2, giving:

$$a^2 = 2(r\text{MZ} - r\text{DZ}) \quad (6)$$

$$c^2 = 2r\text{DZ} - r\text{MZ} \quad (7)$$

Although path analysis is most commonly carried out with twin data, the approach is perfectly general and can be applied to other types of relative pairs. It can also incorporate other types of observations such as direct environmental measures.

2.6 Structural Equation Models

Structural equation modeling enables formal testing of the extent to which the genetic and environmental effects described above contribute to the variance of the phenotype, or the variance of liability of categorical phenotypes. This is typically performed using computer programs such as LISREL or Mx, which use an iterative process to test which estimates for each of the parameters best explain both the observed data and the expected variance and covariance values. These expected values are calculated by the program using information regarding the causes of covariation, for example, that the covariance between MZ twins results from genetic and common environmental effects, and that between DZ twins is due to half the genetic effects and all the common environment. The best fitting model is the one in which there is maximum agreement between the expected and observed covariances. This is achieved by maximizing a likelihood function or minimizing the goodness-of-fit χ^2.

A principle of parsimony is adopted whereby there is an attempt to explain the observed data with as few parameters as possible. Thus nested models, in which parameters are dropped, are tested and compared with the full model to see if the remaining parameters can account for all the similarity between the twins without significantly worsening the fit of the model.

Model fitting need not be restricted to explaining the cause of phenotypic variance and covariance. It can also be used, for example, to identify the existence of qualitative and quantitative sex differences, identify the causes of phenotypic comorbidity, assess sibling interaction effects, and tease out gene–environment interaction effects.

3 Molecular Genetics

3.1 Animal Studies

Animal models are useful in the identification of genes with a role in behavior since it is possible to modify and manipulate both the genome and environment of laboratory animals in a way that is not possible in human samples. Other mammals have a high level of genetic homology with humans, and also display certain behaviors that are analogs of human traits. For example, the mouse genome shares approximately 85% homology with humans and mice show behaviors analogous to such human behaviors as anxiety, aggression, and hyperactivity.

Animal studies use inbreeding and selection studies to identify the presence of

a genetic influence on behavior. Inbreeding, the mating together of close relatives such as siblings, when repeated over many generations, creates animals that are virtually identical. Consequently, differences within strains are largely or entirely due nongenetic effects, whilst differences between strains kept in similar environments are due to genetic effects. Inbreeding has been used to demonstrate a genetic basis to numerous mouse behaviors such as fearfulness, held to be a model of human anxiety, and ability to solve problems such as mazes, which provides analogies for components of human intelligence. Currently, there are over 100 inbred strains of mice commercially available. Mouse models are, of course, limited when it comes to more complex human behaviors and cannot shed direct light on behaviors involving speech and language. Another limitation is that inbred strains may not represent the behavioral repertoire of naturally segregating genetic populations. Another practical problem is that inbreeding depression may result in reduced infertility, interfering with breeding of laboratory strains.

The ability to select for a trait is only possible when there is an underlying genetic contribution. Thus, if we are able to selectively breed for a trait, we can infer a genetic component. For example, selection studies have been carried out with regard to so-called open field activity in rodents, where the rodents are introduced to an enclosure that is open at the top, often in the form of a cage with beams of light transmitted near the floor to record activity. A rat or mouse that displays low levels of activity and frequently ''freezes'' and defecates in an open field is thought to display the equivalent of high anxiety, whilst one that is highly active in an open field and shows less frequent defecation is thought to have low anxiety. By selectively mating together animals that show high activity, and mating together those that display low activity it has been possible to develop behaviorally distinct lines, the best known of which are the ''Maudsley reactive'' and ''Maudsley nonreactive'' rats.

There are a number of methods used to identify genes using animal models. These include studies of transgenic, knockout, and recombinant inbred strains. In transgenic mice, genes from another species, such as humans, are inserted into the mouse genome, and the effects of the gene can be observed. Genes such as the Dopamine D1 receptor gene has been implicated in anxiety and hyperactivity using transgenic mice.

Knockout mice result from eliminating activity of genes thought to be influential and observing the effect this has on the animal's behavior. This technique has been used to show that the monoamine oxidase A gene and the nitric oxide synthase gene both play a role in mouse aggression as knockout mice for each of these displayed higher rates of aggression compared to the wild-type mice.

By mating together a single male and female from two different inbred strains and then carrying out brother sister matings for 20 or more generations, it is possible to develop a recombinant inbred (RI) strain. Like any form of inbred strain, RIs are essentially identical and each contains only two alleles for each locus, one from each of the original inbred strains from which they were derived. It is possible to identify which of the progenitor strains each of the alleles at a locus originate from. When two alleles at different loci originate from the same progenitor strain, they are said to be concordant, and when they are from different progenitors, they are said to be discordant. The greater

the physical distance between two alleles, the greater the chance of discordance. RI strains are ideal for studying linkage and have a number of advantages. As they are genetically identical, all people working on an RI strain are essentially using the same animal and thus each strain needs to be genotyped only once. Moreover, the intensive inbreeding reduces the influence of environmental effects on a phenotype, making it possible to study phenotypes of low and moderate heritability and complex traits.

3.2 Human Studies

Quantitative genetic approaches to behavior can tell us whether genes are involved in a particular trait and provide us with estimates of how much genes contribute. However, such statistical approaches are not ends in themselves and molecular genetic approaches are the next stage allowing us to move on to discover what genes are involved and how they act in concert with the environment.

Broadly, there are two approaches to identifying the genes involved in complex traits. These are candidate gene studies and positional cloning. Candidate genes are those that encode for proteins where there is a prior hypothesis that they might be involved in a trait or disorder. Positional cloning starts out with no prior hypothesis except that there is a genetic contribution to the trait. The locations of genes are then inferred by linkage and association (Sect. 3.2.1) and then this positional information is refined until the genes are pinpointed and identified. Since at least half of all genes are expressed in the brain, the potential number of behavioral candidate genes is overwhelming and has to be narrowed down in some way. The most common approach with regard to psychiatric disorders has been to draw up a list of candidates based on informed guesswork with useful leads being provided by the mode of action of drugs. For example, all of the standard drug treatments used in schizophrenia, the ''typical'' antipsychotics such as Chlorpromazine and Haloperidol, are known to block a class of receptors for the neurotransmitter dopamine, called D2 receptors. The newer ''atypical'' antipsychotic drugs (e.g. Clozapine and Olanzapine) block both dopamine and serotonin receptors in the brain, most importantly, a type of receptor designated 5HT2A. Consequently, researchers have attempted to discover polymorphisms (variants) in the 5HT2A receptor gene and in D2 receptor genes, and compare their frequency in cases affected by schizophrenia and controls who do not have the disorder. The results overall suggest a small but significant effect of the variant in the 5HT2A receptor gene and a dopamine receptor gene DRD3, a member of the D2-like family.

Such investigations are examples of allelic association studies, to which we will return to discuss in more detail in Sect. 3.2.2. A complementary approach and one that is the starting point for positional cloning is to carry out genetic linkage studies. Linkage studies provide information about the location of genes involved in traits or disorders where the causation is unknown. Researchers can then move from location to gene identification and then to studies of structure and sequence and finally to studies of the gene products themselves.

3.2.1 Linkage Analysis

Loci that are on different chromosomes or that are far apart on the same chromosome obey Mendel's law of independent

assortment, that is, they are transmitted together from one generation to the next, or cosegregate, at a frequency no higher than chance. Loci that are close together tend to depart from chance assortment and, within certain limits, the frequency of recombination, or crossing-over between loci on paired chromosomes is proportional to the physical distance between them. In gene mapping studies, the genome is measured in units called centimorgans (cM) with 1 cM corresponding to a pair of loci showing crossing-over, or recombination, one meiosis in a hundred. The whole genome, averaged across the sexes (there is more crossing-over in female than in male meioses) is about 3500 cM long, with 1 cM roughly corresponding to just under a mega base of DNA (or a million base pairs). Linkage can be detected over relatively large distances, 10 cM or more, so that it is possible to mount a whole genome search using just a few hundred evenly spaced markers. The disadvantage of linkage is that it is capable of detecting only comparatively large effects. Linkage is therefore straightforward in rare, simple Mendelian neuropsychiatric disorders such as Huntingdon's disease or some forms of early-onset familial Alzheimer's disease that show autosomal dominant inheritance. However, in the case of common, complex traits, such as schizophrenia or affective disorders, linkage studies present more of a challenge.

Parametric linkage analysis While in studies of plants or animals under laboratory conditions it may be possible to arrange crosses on a large scale and simply count the numbers of recombinants and nonrecombinants, studies of humans are more complicated. The standard statistical approach to detecting linkage and estimating recombination is to calculate LOD (log of the odds) scores. An LOD score is the common log of the ratio of the probability that a recombination fraction has a certain value of less than one half to the probability that the recombination fraction equals one half. LOD scores are calculated for a range of values of the recombination fraction from 0 to 0.5 and the value that gives the maximum LOD is taken as the most likely value of the recombination fraction. By convention, an LOD of three or more (i.e. odds on linkage of 1000 to 1) are accepted as sufficient support for linkage and an LOD of – 2 (i.e. odds of 100 to 1 against) is accepted as excluding the presence of linkage. Unfortunately, LOD scores were originally intended for simple traits. Therefore, one of the difficulties that besets attempts to detect linkage in psychiatric disorders and other common diseases is that the mode of transmission is unknown. That is, the disease does not usually follow a simple Mendelian pattern of segregation in families.

The LOD score approach can be extended to complex traits by incorporating penetrance parameters. Penetrance is defined as the probability that a particular phenotype will be manifested given a certain genotype. In Mendelian traits, penetrances are always either 0 or 1. For example, if we consider a trait where there are two alleles, A_1 and A_2, and where A_2 is the ''disease'' allele, there will be three possible genotypes A_1A_1, A_1A_2, and A_2A_2. If A_2 is recessive, the three genotypes will show penetrances of 0, 0, and 1 respectively, whereas if A_2 is dominant, the penetrances will be respectively 0, 1, and 1. Complex traits that depart from Mendelian patterns can be modeled using a more general single major locus (SML) approach where penetrances

can take values between 0 and 1. However, in order for linkage studies to be carried out accurately, the penetrance parameters together with the disease gene frequency need to be specified correctly. Otherwise, at best, the estimate of recombination will be incorrect, and at worst, linkage will not be detected even when it is present.

Other problems include possible genetic heterogeneity in common disorders and relative imprecision in defining who is affected or unaffected within families. This is not a difficulty when there are clear-cut cases and clear-cut healthy family members, but common diseases often also show milder or uncertain cases within the same families. The most straightforward way of dealing with these problems has been to concentrate on extended families with many affected members and to make an informed guess at the mode of transmission. It is also assumed that even if there is heterogeneity in the disorder as a whole, there is homogeneity at least within the families. Such simplifying assumptions have worked well with some common diseases, with the most notable success amongst psychiatric disorders being early-onset familial Alzheimer's disease. However, in other disorders such as schizophrenia, concentration on large multiply affected families has produced results that are more difficult to interpret, hence there has been a move toward using nonparametric or ''model-free'' methods of analysis.

Nonparametric linkage analysis The most common approach concentrates on affected sibling pairs. Affected sib pairs may be more representative of a common disorder than subjects found in multiplex pedigrees and, in general, finding families containing affected sib pairs is easier than finding extending pedigrees. However, the real advantage of focusing on sib pairs who are both affected by the disorder is that the statistical analysis is relatively straightforward and robust. Detection of linkage depends on the fact that at any given locus, the probabilities of a pair of siblings inheriting 0, 1, or 2 alleles that are identical by descent are respectively 1/4, 1/2, and 1/4. Greater allele sharing at a marker than would be expected by chance in pairs of siblings who are both affected by the disease suggests that the marker locus is close to a gene conferring susceptibility to the disorder. The unfortunate disadvantage of sib pair methods is that although they are simple and robust, there is a comparative lack of statistical power. Both practical experience and simulation studies suggest that unless the sample sizes are extremely large, linkage is difficult to detect with genes that confer a relative risk of a disorder of much less than about three or account for less than about 10% of a variation in liability to the disorder. Genes with effects as large as that may be rare in common diseases and so, for example, a genome scan for linkage in schizophrenia in almost 200 families effectively excluded any gene having a relative risk of three from most of the genome. The need to detect genes having only small effects has brought about a renewed interest in applying allelic association studies in a more systematic fashion than just focusing on potential candidate genes.

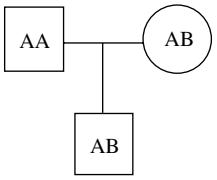
3.2.2 Association Studies

Allelic association is the phenomenon whereby a particular allele at a marker locus is found together with a trait or disorder more than would be expected by chance. In contrast with linkage, the same allele is found across the population rather

than just within particular families. The simplest and most commonly used study design is to compare allelic frequency between affected cases and controls. It has long been known that association can detect those genes that account for as little as 1% of the variance in a trait. However, association only occurs either if the marker itself contributes to the trait or disorder or if a gene contributing to the trait or disorder is so close to the marker locus that there is linkage disequilibrium (LD). LD is the phenomenon whereby alleles at adjacent loci are found in a combination that is undisturbed over many generations of potential crossing-over.

One of the difficulties in interpreting association studies is that recent admixtures of populations can bring about stratification. This occurs when two ethnic groups have different frequencies of a disease and the trait that is being studied and also have different frequencies of marker alleles. Consequently, in mixed populations from these groups, there may be a spurious association unless cases and controls are carefully matched for ethnicity. To overcome the need to carry out case control matching, which may be difficult in some highly admixed populations where there has been much immigration, one can use family based methods with ''internal controls.'' For example, in the transmission disequilibrium test (TDT), trios consisting of an affected offspring and both parents are studied. At least one parent needs to be heterozygous at the marker locus. It is then possible to test the frequency of affected offspring to whom a particular allele is transmitted, with the frequency of those who do not receive that allele. That is, the untransmitted marker alleles are effectively the ''controls'' while the transmitted alleles are the ''case alleles.'' A significant distortion of the chance expectation of transmission of alleles is easily tested by a simple statistic called the *McNemar* χ^2 where a significant result indicates that LD is present. The principles of TDT are shown in Fig. 8.

The drawback of allelic association studies is that LD can only be detected over very short distances and hence many thousands, not hundreds, of markers would be needed to carry out a whole genome scan. There is currently considerable debate over the approximate number of markers that would be required to carry out a genome scan using LD. One controversial suggestion based on simulations suggests that this might be as many as 500 000 markers. However, some empirical studies have shown that in moderately outbred populations, LD can be detected over distances up to 1 cM. Although LD is not evenly distributed across the genome, this would mean that a few thousand markers would probably be sufficient for an initial screen of the genome. Even so, until recently, a genome scan using this number of markers was not feasible, but now the availability of very dense marker maps based on single nucleotide polymorphisms (SNPs)



Allele	Father	Mother
Transmitted	A	B
Non transmitted	A	A

Fig. 8 Transmission/Disequilibrium Test (TDT).

means that it is possible to construct an SNP map across regions of interest (e.g. a region implicated by linkage studies) and narrow it down using case control studies to detect LD. Databases can then be searched for genes within the narrowed region of interest and SNPs selected within such genes to explore them further in case control comparisons. This process, which in effect is a convergence of the positional cloning and candidate gene approaches, is now referred to as the *positional candidate approach* and has been successful, as we will discuss below, in implicating several genes in the etiology of schizophrenia.

4 Applications

Quantitative approaches have now been used extensively in a wide range of behavioral traits and disorders and increasingly, molecular genetic approaches are being applied. Here, we have selected three major examples, one a normal trait and the other two, disorders (or rather groups of disorders). These are general cognitive ability or intelligence, mood disorders and schizophrenia.

4.1 General Cognitive Ability

Intelligence in its various guises is one of the most extensively studied aspects of human behavior. There is now a broad consensus among psychologists that although various types of intelligence can be described and tests devised to measure them, performance on such tests is strongly correlated with a common factor called *general cognitive ability* or ''g.'' Thus, it is has been shown that tasks such as copying a design with wooden blocks (visuo–spatial ability), vocabulary tests (verbal ability), remembering figures (memory), and comparing lists of objects (processing speed) all correlate with ''g.'' Commonly used tests provide measures of general intelligence quotient (IQ) as well as specific abilities including the Wechsler Adult Intelligence Scale (WAIS) and the Wechsler Intelligence Scale for Children (WISC).

Quantitative genetics and cognitive ability
Family studies of IQ and ''g'' demonstrate moderate to high correlations of around 0.4 to 0.5 for first-degree relatives. More distant relatives such as cousins typically show correlations in the order of 0.15. Although such a pattern suggests the involvement of genes, it is not on its own sufficient proof. In fact, nearly all of the twin studies performed in childhood suggest that the familial correlation in IQ is partly the result of genes and partly the result of shared environment. For example, identical twins reared together show very high correlations for g, on average around 0.85. This is somewhat lower, at around 0.7, in identical twins reared apart. Similarly, DZ twins reared together show an average correlation for g of about 0.6, but this falls to an average 0.3 in DZ twins reared apart. It can be shown using the sort of structural equation models that have been discussed earlier that this pattern of correlations corresponds to a heritability of around 50% with about 25% of the variance explained by shared environment and the remainder explained by nonshared environment.

Adoption studies in childhood are almost completely consistent with the twin results in that adoptive siblings show a correlation for g of around 0.25 compared with a correlation of 0.5 in biological siblings

reared together. The pattern, however, is rather different in adults and, surprisingly, it is only comparatively recently that much attention has been focused on this. It turns out that biologically unrelated individuals who are raised as siblings have an average correlation of zero for general intelligence when measured as adults. Twin studies similarly show that the heritability of IQ steadily increases in adolescents compared with children and in adults compared with adolescents. At the same time, the effect of shared environment decreases. Very recent studies of twins in late life show that the nondemented elderly have the highest heritability for general intelligence of all age groups at around 60% with no evidence of a shared environmental effect.

In summary, quantitative genetic studies have recently converged on a consensus that general intelligence is at least moderately heritable and perhaps highly heritable, particularly in late adulthood. Much interest has now begun to shift towards the goal of actually being able to locate and identify genes involved in cognitive ability.

Molecular studies: searching for "IQ-QTLs"

It is broadly accepted from the pattern of inheritance of general cognitive ability that it is likely to be a highly polygenic trait. That is, there is likely to be a contribution from many genes each of which on its own has only a very small effect. If this assumption is correct, then linkage studies will be very difficult and therefore almost all the attention has focused on allelic association. A pioneering study was by Plomin and colleagues who in 1995 published results on 100 polymorphisms selected on the basis that they were at or near genes that were expressed in the brain. A comparison of allele distributions was made in three groups of subjects showing high, middle, and low scores on IQ tests and positive results were followed up on a replication sample. Although there were some promising preliminary findings including a locus on chromosome 6p and an association with a mitochondrial polymorphism, these failed to replicate on an independent sample.

The same group then embarked on an ambitious project attempting to search the whole genome, chromosome by chromosome, for linkage disequilibrium using a highly polymorphic set of microsatellite markers. Plomin and colleagues also adopted an innovative approach using DNA pooling in which the DNA from very high IQ subjects was combined in one pool and this was compared with the DNA from a pool of subjects with average IQ. The aim here was to achieve a rapid way of testing many markers. Thus, the initial study searching for genes having an effect on IQ used around 2000 markers on 200 unrelated subjects with high IQ and 100 with average IQ. This would have entailed 600 000 individual genotypings, but with DNA pooling of the high-IQ and average-IQ groups, the initial genotyping was reduced to a more manageable 4000. Positive results were then subsequently followed up by individual genotyping. To date, there are no definite positive associations that have been discovered with general cognitive ability that have replicated on all samples. However, there have been some intriguing, suggestive findings, for example, of an association with a variant in the insulin-like growth factor receptor 2 gene (*IGF2R*). While these results may be worth pursuing further, it should be emphasized that *IGF2R* is not, as some popular press reports suggested, the "gene for" IQ. In fact, the *IGF2R* association reported by the group of Plomin et al. appears at best to account

for about 2% of the variance in general cognitive ability.

4.2 Schizophrenia

Quantitative genetics of schizophrenia As already noted, there is consistent evidence that schizophrenia is more common in the relatives of schizophrenics than in the general population. The lifetime risk of schizophrenia is surprisingly constant in all of those countries for which figures are available at around 1% of the population. This compares with around 10% in the siblings and offspring of schizophrenics. It is at first sight perhaps curious that the risk in parents of schizophrenics is much lower at around 5%, but this is probably because of a ''censoring'' effect. Schizophrenia is a disorder with a markedly adverse effect on the ability of a sufferer to find a mate and procreate. This means that the parents of schizophrenics, who are themselves schizophrenic, will almost all have their onset *after* having had their children. Consequently, the period of risk for developing schizophrenia is reduced and individuals who have both had children and developed schizophrenia are likely to consist of comparatively late-onset cases.

Familiality does not, of course, on its own prove that schizophrenia has a partly genetic basis. Indeed, schizophrenia was at one time among the hotly contested topics in the ''nature versus nurture'' debate. This came to its height in the 1960s when ''antipsychiatrists,'' such as the followers of R. D. Laing, criticized the very concept of schizophrenia, taking the somewhat romantic view that the manifestations of the disorder, hallucinations, delusions, and a distorted view of reality, could be seen as a ''sane response to an insane world.'' Subsequently, adoption and twin studies have convinced all but the most obdurate skeptics that schizophrenia cannot be explained purely as a reaction to an adverse environment. As Seymour Kety, one of the leaders of an influential group of Danish–American adoption studies commented, ''If schizophrenia is a myth then it is a myth with a strong genetic basis.'' We have already reviewed the adoption study data (Table 2). The twin data are also completely compatible with important genetic influences, and the five most recent twin studies (four from Europe and one from Japan) show concordance rates in MZ twins of 41 to 65% compared with 0 to 28% in DZ twins. A meta-analysis of these data suggested a heritability in excess of 80%.

Molecular genetics: finding the susceptibility genes Given that there is consistent evidence of a strong genetic effect, it might be expected that the business of locating and identifying genes should prove to be relatively straightforward. However, schizophrenia appears to be a polygenic disorder where single-gene forms are rare or perhaps nonexistent and where each of the contributory genes, on its own, has a very small effect. Indeed, attempts to map genes involved in schizophrenia date back to almost 50 years and there were several attempts to discover schizophrenia-associated genes in the ''premolecular'' era using what are now called classical genetic markers such as blood groups and human leukocyte antigen (HLA) types. More recently, attention has turned to polymorphisms in functional candidate genes and, as we have already mentioned, there is evidence of a small but consistent effect resulting from variants in the serotonin *5HT2A* receptor gene and dopamine

DRD3 receptor gene. There has also been renewed interest in another gene involved in dopamine neurotransmission, catechol-O-methyltransferase (*COMT*). *COMT* inactivates catecholamines, including dopamine, by methylating their m-hydroxy group. A functional *COMT* gene polymorphism has been described that influences enzyme activities and the high-activity allele (*val*-108) has been found to be associated with schizophrenia in some studies. This is of particular interest because schizophrenics, compared with controls, on average show reduced metabolism in the prefrontal lobe of the brain and do less well on cognitive tests that are designed to test prefrontal function. Otherwise healthy subjects who have the high-activity allele fair less well in such tests and have less efficient prefrontal physiology than those who have only the low-activity (*met*-108) allele. Unfortunately, the *val/met* polymorphism association with schizophrenia has not proved consistent across studies. The largest single study to focus on *COMT* suggests that there is a weak but highly significant association with schizophrenia, but this results from a set of variants in a haplotype in a different part of the gene.

Perhaps of even greater interest, several new positional candidates, genes that are involved in neurochemical pathways and/or neurodevelopmental processes that are of relevance to schizophrenia, have been implicated in linkage regions. One of these, neuregulin-1 (*NRG1*), maps to chromosome 8p, a region of the genome implicated in schizophrenia in a number of studies including one based on Icelandic families. The Icelandic researchers performed an association analysis across the region that gave significant evidence of an effect of a variant in *NRG1*. The *NRG1* association with schizophrenia was subsequently replicated in Scottish patients and controls. Mice in which one copy of *NRG1* or of the gene for its receptor *ErbB4* have been ''knocked out'' show some behaviors that occur in schizophrenic patients, including a response to simple stimuli called prepulse inhibition. These changes can be partially reversed in the mice with the antipsychotic drug Clozapine. The mutant mice also have fewer functional receptors for the excitatory amino acid glutamine of the NMDA type than do wild-type mice.

A completely novel gene encoding for a protein called G72 also appears to have a role in NMDA receptor function. The *G72* gene maps to chromosome 13q to a region that again has been implicated in several linkage studies. In a study involving Canadian patients, which was then replicated in cases from Russia, the region was again narrowed down by linkage disequilibrium mapping. Potential genes in the narrowed region were then identified by searching computer databases. After experimental annotation using RT-PCR, two genes were identified, one of which, *G72*, was found to be expressed in the human brain. It is also of interest that given the quintessentially human and language-based character of schizophrenic symptoms, *G72* appears to be found only in primates. Furthermore, the longest transcript of the gene in the chimpanzee brain is only about half that of its human counterpart, perhaps suggesting rapid evolutionary change. Using a way of identifying interacting proteins called the yeast 2 hybrid method, an interaction with the enzyme D-amino acid oxidase (DAAO) was found. DAAO is also expressed in the brain and oxidizes D-serine, which in turn has an activating effect at an NMDA receptor.

A third linkage region, this time on chromosome 6p originally identified by

a large study of Irish families, contains a gene called dystrobrevin-binding protein-1 or dysbindin, which again contains variants that appear to be more common in schizophrenics than in controls. Dysbindin is widely expressed in mouse brain, and by binding to dystrobrevin, appears to play a role in synapse formation and maintenance and possibly in NMDA receptor clustering.

A region on chromosome 22q has been implicated not just by linkage studies but also by studies of individuals in whom there is a micro deletion of the region. Depending on the size of the deletion, those who carry it present with an overlapping set of syndromes of which the central one is called velo-cardio-facial syndrome (VCFS). About a quarter to a third of individuals who have VCFS also show schizophrenic-like symptoms. Interestingly, the VCFS region contains the *COMT* gene, but some studies of schizophrenia, particularly the early-onset type, have suggested an association with variants in another gene, proline dehydrogenase (*PRODH2*). There is again some evidence that *PRODH2* is involved in the modulation of glutamine transmission in the brain at NMDA receptors.

The fact that all of these genes have an effect on glutamate transmission seems unlikely to be coincidental. Glutamate receptors are of two broad types – those such as the NMDA receptor that are ion channels (''ionotropic'') and those that are coupled to a class of intracellular messengers called g-proteins (''metabotropic''). G-protein signaling is in turn influenced by a class of proteins called regulators of g-protein (RGS). One such protein, RGS4, has been shown to have altered expression in schizophrenic brains compared with controls. Subsequently, a haplotype, a set of variants in the *RGS4* gene, has been found to show differences between patients and controls. *RGS4* is also relevant to other g-protein coupled receptors including dopamine receptors belonging to the D2 family.

4.3 Mood Disorders

The major mood disorders belong to two main groups, bipolar affective disorders and unipolar depression. Bipolar disorder is so called because there are both, episodes of mania (characterized by elation, over-activity, disinhibition, and often reckless behavior) and episodes of depression (characterized by low mood often accompanied by sleep disturbance, appetite and weight loss, and suicidal thoughts). Unipolar disorder, also called depressive disorder, consists of episodes of depression alone. Depressive disorder is very common. Illness that is sufficiently severe to warrant referral to a psychiatrist has a lifetime risk in the general population, of around 6 to 8%. Less severe forms are even more common. Affected women outnumber men by about 2 : 1. By contrast, there is no sex difference in the frequency of bipolar disorder, which is a less common condition affecting around 0.5 to 1% of the population per lifetime.

Quantitative genetics of mood disorder

Both forms of disorder show a marked tendency to aggregate in families. The majority of studies show a stronger familial effect with bipolar disorder, although some more recent studies, particularly those focusing on severe depression, find that unipolar disorder is almost as familial. A major and consistent difference in all studies is that index cases with unipolar disorder have an excess only of unipolar depression among their relatives, whereas

index cases with bipolar disorder have an excess of relatives both with bipolar disorder and with unipolar depression.

In contrast with schizophrenia, the adoption data on affective disorders are fairly sparse, but the most carefully conducted studies suggest that the familial clustering of these disorders largely results from genetic effects. This is supported by twin research. In recent studies of unipolar depression, there is consistently higher concordance in monozygotic than in dizygotic twins. The effect appears to be stronger in more severe or recurrent depression and model fitting studies aimed at estimating heritability suggest that this is around 70% in studies where the index cases have been ascertained via hospitals or clinics. If the depressed index cases are ascertained via population surveys, perhaps consisting of milder disorder, the heritability is typically around 30 to 40%.

The twin study model fitting results also suggest that whether the sample is obtained clinically or is population-based, the environmental effects are all of the nonshared kind. There have been several studies attempting to examine the interplay between genetic and environmental risk factors in unipolar depression. There is a great deal of evidence supporting the common sense hypothesis that onsets of depression are frequently associated with unpleasant events. However, there is no evidence that depression that is associated with adversity is any less familial than depression that arises ''out of the blue.'' There is also considerable evidence from studies of families and twins that life events are not completely randomly distributed in the population. Some individuals are more prone to life events than others and people who score high on personality traits designed to measure dimensions such as extraversion or novelty-seeking seem to have more eventful lives than those who score low on such trait measures. These personality traits have been found to show both positive correlations in siblings and, in twin studies, to be heritable. Therefore, it is perhaps not too surprising that at least some forms of life events also appear to be familial. For some events, the familial effect is purely environmental. For example, the death of a parent affects both members of a pair of siblings or twins. Nevertheless, several studies indicate that some events reflect the influence of genetic factors rather than shared environment.

Molecular genetics: searching for ''blue genes'' Bipolar disorder has been the subject of quite a number of linkage studies including whole genome scans. The data are less extensive than those for schizophrenia and recent meta-analyses would suggest that they are much less clear-cut. Despite this, regions of interest have been identified on chromosomes 13q and 22q, which overlap those that have been implicated in schizophrenia. Although the conventional view is that schizophrenia and bipolar disorder are largely different genetically, families have frequently been described containing sufferers from both conditions and occasionally identical twins or triplets have been described who have nonidentical psychoses. A recent twin study using multivariate structural equation modeling looked at symptom patterns rather than conventional diagnoses, that is, subjects were classified as having a bipolar syndrome, schizophrenia, or schizoaffective disorder, an intermediate form. Instead of assigning an exclusive diagnosis, subjects were classified according to the symptom pattern as having one, two, or all three disorders. The analyses suggested a large

overlap in the genes contributing to all three disorders as well as the existence of specific genes contributing to the liability of either schizophrenia or bipolar disorder. The findings are therefore consistent with linkage study findings pointing to an overlap in the genomic regions that contain schizophrenic and bipolar genes. As we write, no studies have yet been published on bipolar disorder and *G72* or *DAAO*, the genes on chromosome 13q discussed earlier in relation to schizophrenia. Nor have there been any published studies on PR0DH2 and bipolar disorder on the chromosome 22q genes implicated in schizophrenia. However, *COMT* variants have been implicated in bipolar disorder, particularly inpatients who show rapid cycling, that is, those having four or more episodes per year.

Molecular genetic studies are much less advanced in unipolar disorder, although several large-scale linkage and association studies are currently under way. To date, the most provocative results have been based on the serotonin transporter gene. One of the ways in which serotonin is cleared from the synapse is by reuptake into the presynaptic neuron. This is the site of action of the antidepressant drugs called selective serotonin reuptake inhibitors of which fluoxetine (Prozac) is probably the best-known example. The serotonin transporter gene contains a common variable number tandem repeat (VNTR) polymorphism within one of its introns, as well as a common variant in the promoter region that has been shown to effect levels of gene expression. Both variants have been implicated in association studies of mood disorders and the promoter polymorphism may also be associated with the personality trait of neuroticism, which may in turn be associated with vulnerability to depression.

5 Future Directions

Behavioral genetics is now moving into an era of behavioral genomics, offering an improved understanding of the neurobiology of disease. Not only is the complete human genome sequence known but there are also complete genome sequences or draft sequences available on over 60 species. Comparing genomes across species and noting differences in those genes that have been conserved will show the major variations between species and offer an understanding of the basis for neurobiological and hence behavioral evolution. Knowing the structure and function of all human genes has been compared with the discovery of a ''periodic table of life.'' It paves the way for a series of paradigm shifts where the emphasis moves from the structure of the genome to functional genomics and to proteomics, the study of proteins, at a functional level. A striking example of how one complex aspect of human behavior, circadian rhythms, can be dissected and its basis understood at a molecular level is given by the recent discovery of new ''clock genes,'' simply by the analysis of the draft sequence of the human genome that was discovered when searching for genes with a high similarity to known clock genes originally discovered in mice or fruit flies.

Even before the publication of the draft sequence of the human genome, discoveries arrived at by positional cloning in Alzheimer's disease (AD) have begun to provide important new understandings of the neuropathological mechanism. Although Alzheimer's disease has a characteristic neuropathology that was described at the beginning of the twentieth century, the problem of discovering its pathogenesis did not appear to have a tractable solution until the discovery of the role

of mutations in the amyloid precursor protein and presenilin. Interestingly, although presenilin1 on chromosome 14 was identified by positional cloning, presenilin2 was discovered essentially by its homology with presenilin1 and subsequently was demonstrated to have an etiological role by linkage analysis. As with the discovery of new clock genes, we can expect the discovery of families of genes involved in abnormal and normal behaviors to become more commonplace.

Identification of genes and gene products involved in psychiatric disorders will have important implications for pharmacotherapy in two ways. The first of these is in directing drug discovery. At present, the drugs used in the treatment of psychiatric or other central nervous system diseases have their actions at a limited number of target sites that include cell surface receptors, nuclear receptors, ion channels, and enzymes. It is likely that detecting genes involved in the pathogenesis of psychiatric disorders will identify new targets, some of which fall within these categories and some of which have not thus far been included as target sites for drug action. In addition to targeting of treatments, advances in genomics will allow the tailoring of treatments. There is already some evidence that the response to a typical antipsychotic such as Clozapine is influenced by an individual genotype at the serotonin 5HT2A receptor. It is also well established that the rate at which most psychoactive drugs are metabolized is influenced by genetic factors, in particular, genes that code for a family of enzymes called the cytochrome P450 system. This may be relevant to the development of side effects as well as to treatment response. This whole area of pharmacogenomics is still comparatively novel. It holds enormous promise for individual tailoring of treatments that will be a major advance over the current trial and error approach that the clinician is now saddled with.

There has been a degree of public concern that the current pace of advance will tend to ''geneticize'' common diseases and encourage deterministic attitudes. In particular, worries have been expressed that insurance companies may wish to force DNA testing on individuals thought to be at high genetic risk of disorder. While prediction with a high degree of accuracy is already possible for rare early-onset dementia such as Huntington's disease or the single-gene forms of AD, this is not possible for complex disorders. For example, the apolipoprotein €4 allele, despite the confirmed association with risk of late-onset AD in the general population, is of limited value as a predictor at an individual level. The situation is likely to prove even more complicated with disorders such as schizophrenia. At best, DNA-based tests may be used to modify the predicted risk in individuals who are already at high risk because of having a schizophrenic close relative. However, it is unlikely that risk prediction will ever be better than about 50% accurate, since genetically identical individuals, MZ twins, are discordant for schizophrenia 50% of the time. This means that DNA-based population screening for complex psychiatric disorders (including AD of late onset) will never become a reality, but the option of offering screening to high-risk individuals probably will, with the caveat that such testing will refine risk prediction but not give clear yes/no answers. Given that most common diseases, and not just psychiatric ones, will depend upon the combined action of multiple common gene variations together with environmental risk factors, batteries of genetic tests will be of limited usefulness to insurance companies and are not likely to be widely employed.

Finally, the other potentially worrying aspect of psychiatric disorders becoming ''geneticized'' is, it has been suggested, an increase in stigma. Of course, just the opposite could be the case, so that increasing knowledge about the causation of disorders may serve to demystify them and therefore make them, in the public eyes, something that is more tangible and acceptable. Part of postgenomic psychiatry's impact on disorders such as schizophrenia, bipolar affective disorder, and depression might therefore be to legitimize them as ''real'' diseases rather than, as is all too often the case, their being seen as phenomena that result from personal failing or weakness. AD might be taken as a good example of how public perceptions clearly have changed. ''Becoming senile'' in old age was once seen by many as somehow morally reprehensible, whereas it is now acceptable for the families of a past President of the United States or a famous novelist such as Iris Murdoch to ''come out'' and admit that they suffer from AD. In the authors' present view, this could turn out to be a general effect. Therefore, rather than an increasing stigma, it is quite possible that the ultimate effect of genetic research on the public image of psychiatric diseases will be wholly positive.

Keywords

Lysosome
An acidic organelle containing hydrolytic enzymes.

Vacuole
A large lysosome-like organelle found in yeast and plants.

Mannose 6-Phosphate Receptor
One of two proteins in mammalian cells that recognize lysosomal lumen proteins tagged with mannose 6-phosphate.

Phosphoinositides
Lipids that act as second messengers and regulate vesicular traffic.

Lysosomal Storage Disease
Defects in lysosomal enzyme activity or targeting that result in the lysosomal accumulation of undigested materials.

Abbreviations

ALP	alkaline phosphatase
AP	adaptor protein
Aph	autophagosome
API	aminopeptidase I
Apg	autophagy
ARF	ADP-ribosylation factor
Cma	chaperone-mediated autophagy
COP	coatomer protein
CPY	carboxypeptidase Y
Cvt	cytoplasm-to-vacuole targeting
ER	endoplasmic reticulum
FBPase	fructose-1,6-bisphosphatase
FYVE	Fab1, YGLO23, Vps27, EEA1
GGA	Golgi-localizing, gamma adaptin ear homology domain, ARF-binding
Hsp70	heat shock protein of 70 kDa
Hsc70	the constitutively expressed hsp70

IGF	insulin-like growth factor
LAMP	lysosome-associated membrane protein
LIMP	lysosomal integral membrane protein
M6P	mannose 6-phosphate
M6PR	mannose 6-phosphate receptor
MVB	multivesicular body
NSF	*N*-ethylmaleimide sensitive factor
PI	phosphotidylinositol
PI3P	phosphotidylinositol-3-phosphate
Rab	ras-related GTPase
t-SNARE	target membrane soluble *N*-ethylmaleimide sensitive attachment receptor
V-ATPase	Vacuolar proton-pumping ATPase
Vam3p	a t-SNARE in yeast
Vid	Vacuolar import and degradation
Vps	vacuolar protein sorting
v-SNARE	vesicle membrane soluble *N*-ethylmaleimide sensitive attachment receptor

Lysosomes are organelles that are surrounded by a single membrane and contain many hydrolases that are most active at an acidic pH. The pH within the lysosomal lumen is usually maintained between 5.0 and 5.5 by a multisubunit, proton-pumping ATPase in the lysosomal membrane of mammalian cells and in the vacuolar membrane of yeast. Other organelles having some of the properties of lysosomes include late endosomes and multivesicular bodies. However, these organelles have protein and lipid constituents at least partially distinct from lysosomes.

Enzymes in the lysosomal lumen are targeted to that location by mannose 6-phosphate (M6P) carbohydrate modifications in the case of mammalian cell lysosomes or by linear peptide sequences for the yeast vacuole. Integral membrane proteins within the lysosomal and vacuolar membranes are targeted to that location due to critical tyrosine or dileucine peptide motifs in cytosolic regions of the proteins. These motifs interact with vesicle coat protein complexes that concentrate the proteins into vesicles destined for fusion with lysosomes. Peripheral lysosomal membrane proteins generally interact strongly with one or more integral membrane proteins and/or lipids.

Lysosomes account for 1 to 15% of cell volume and of cell protein in mammalian cells and 30 to 90% of cell volume in fungal and plant cells. This variability depends on cell type and physiological status. The morphological appearance of lysosomes also varies from vesicular to a more complex tubular lattice. Lysosomes are responsible for degrading both extracellular and intracellular proteins as well as other macromolecules.

The role of lysosomes in overall intracellular protein degradation depends on the cell type and nutritional conditions. Lysosomes are responsible for most protein degradation in liver and kidney, and certain lysosomal pathways of proteolysis are activated in response to nutritional deprivation. On the other hand, lysosomes play a

minor role in protein degradation in skeletal muscle and lymphocytes, where the ubiquitin-proteasome proteolytic pathway predominates. Lysosomal pathways of proteolysis operate to some extent in all eukaryotic cells except in mature red blood cells that do not contain organelles, and there are at least six different pathways by which proteins can be delivered to lysosomes for digestion.

1 Lysosome Structure

Lysosomes are usually spherical organelles surrounded by a single membrane. There are 50 to 1,000 lysosomes per mammalian cell, but a single large or multilobed lysosome called the *vacuole* in fungi and plants. Lysosomes can be quite heterogeneous in appearance and are difficult to identify on the basis of purely morphological criteria. In fact, spherical lysosomes in many cell types are able to fuse into a tubular network.

The lumen or matrix of the lysosome contains approximately 50 hydrolases most of which are optimally active at acidic pH. The concentration of some of these hydrolases is estimated to be in the range of 100 to 200 mg mL^{-1}. The lysosomal lumen also contains a molecular chaperone of the heat shock protein of 70-kDa (hsp70) family. The vacuolar lumen of yeast and plant cells also serves as storage sites for amino acids, polyphosphates, and other compounds.

The lysosomal membrane is typically a single bilayer. It contains phospholipids, including sphingomyelin, relatively high concentrations of cholesterol, and lysobisphosphatidic acid. This lipid is also found in late endosomes and multivesicular bodies. The lysosomal membrane also contains many different proteins. The *v*acuolar proton-pumping ATPase (V-ATPase) is composed of five different integral membrane proteins and eight different peripheral membrane proteins. Some of each class are present in multiple copies per functional complex. The V-ATPase subunits are not restricted to lysosomal membranes since they can also be found in transport vesicles, endosomes, Golgi, secretory vesicles, and the plasma membrane.

Lysosomal membranes also contain several transporters. Several different sugar transporters have been described that can transport monosaccharides produced in mammalian lysosomes by digestion of glycoconjugates. There is also a polymannose transporter in the lysosomal membrane that transfers oligosaccharides from the cytosol to the lysosome for digestion. Most amino acids exit lysosomes after proteolysis through general or specific amino acid transporters. A cystine transporter, cystinosin, is an integral lysosomal membrane protein that when mutated leads to cystinosis.

Lysosome-associated membrane protein (LAMP) type 2a (LAMP2a) is a receptor for protein substrates of chaperone-mediated autophagy (Cma; see Sect. 5.6). LAMP2a multimerizes in the lysosomal membrane and may form the protein translocon as well as act as the substrate receptor. Another isoform of LAMP2 formed by alternative splicing, LAMP2b, is required for docking or fusion of autophagic vacuoles and lysosomes, a critical step in macroautophagy (see Sect. 5.3), so

LAMP2a and LAMP2b are required for the operation of two different pathways of lysosomal proteolysis. A role for the third splicing isoform, LAMP2c, is not known.

The LAMP2s, like LAMP1 and lysosomal integral membrane proteins (LIMP)s, are integral proteins with most of the protein facing the lysosomal lumen. This portion of the protein is highly glycosylated, and this glycosylation protects the proteins from rapid digestion by the battery of lysosomal proteases. These glycoproteins may also protect the inner leaflet of the lysosomal membrane from digestion by lumenal lipases.

A recent report of detergent-resistant lipid raft microdomains in the lysosomal membrane suggests an additional level of complexity to lysosomal membrane structure. The physiological significance of such microdomains remains to be determined.

Certain specialized cells also contain lysosome-related organelles that are thought to be made by pathways similar to those for lysosomal biogenesis. They contain not only lysosomal proteins but also additional proteins. Such lysosome-related organelles include melanosomes within melanocytes and retinal pigment epithelium and lytic granules within cytotoxic T-lymphocytes and natural killer cells. The acrosome of sperm is also a lysosome-related organelle.

2
Biogenesis of Mammalian Lysosomes

Both lumenal and membrane lysosomal proteins contain specific targeting signals that are required for their correct localization in lysosomes. Receptors or vesicle coat proteins recognize these targeting signals and play critical roles in trafficking the proteins to lysosomes.

2.1
Proteins in the Lumen

Most lysosomal proteins that are soluble within the lysosomal lumen travel through the protein secretory pathway. That is, they are synthesized by polysomes that are associated with the endoplasmic reticulum (ER). They typically have a cleavable membrane-spanning signal sequence that is required for their translocation into the ER lumen. In the ER, the signal sequence is cleaved, and the resulting processed protein is glycosylated. The protein is packaged into coatomer protein (COP) II-coated vesicles and transferred to the Golgi where it is recognized by a phosphotransferase enzyme that transfers *N*-acetyl-glucosamine-1-phosphate to one or more mannose residues on the lysosomal enzyme. A glucosaminidase in the Golgi removes the glucosamine to generate the M6P.

The phosphotransferase recognizes the sugar group and the features of the polypeptide to identify the protein as belonging to lysosomes. The features of the protein that are recognized are not linear but appear to result from protein folding. Multiple lysine residues in a particular chemical environment and the distance from the carbohydrate group appear to be important determinants of phosphotransferase recognition (Fig. 1).

Transfer of the lysosomal protein through the Golgi may be by COPI-coated vesicles. Alternatively, the Golgi may be dynamic with enzyme distribution determined by forward membrane flow and retrograde protein retrieval, a process termed *cisternal maturation*.

All forms of vesicular transport require specific *v*esicle membrane *s*oluble *N*-ethylmaleimide sensitive *a*ttachment *re*ceptor (v-SNARE) and *t*arget membrane

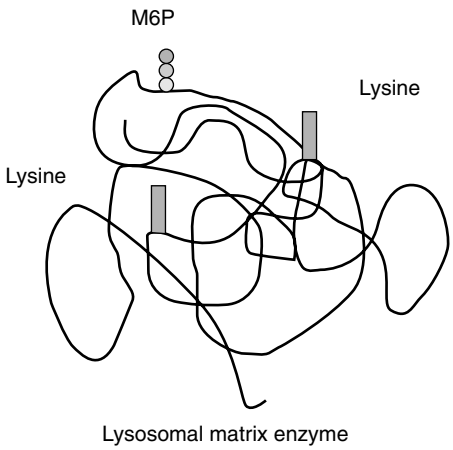

Fig. 1 Proposed recognition elements for the phosphotransferase on a lysosomal matrix protein. Both mannose sugars and lysines within a certain distance from the carbohydrate are recognized by the phosphotransferase enzyme. The lysines may also be in a particular chemical environment created by neighboring amino acid side chains.

*s*oluble *N*-ethylmaleimide sensitive *a*ttachment *re*ceptor (t-SNARE) proteins along with their regulatory proteins, ADP ribosylation factor (ARF) and ras-related GTPases (Rabs). The Rabs are especially important in ensuring specificity of vesicle docking. In order for vesicle fusion to occur, the v-SNARE and t-SNARE first have to be pried apart. This is accomplished by *N*-ethylmaleimide sensitive factor (NSF), a protein complex that is an ATPase.

The M6P is recognized by a M6P receptor (M6PR). There are two types of M6PR in most cells, and both are integral membrane proteins associated with late endosomes, Golgi, and the plasma membrane. One is 215 kDa and binds proteins marked with M6P independently of divalent cations. The other is 46 kDa, and its binding to lysosomal proteins is highly dependent on the presence of divalent cations. These different M6PRs may recognize different lysosomal enzymes and/or be differentially regulated. In the trans-Golgi network, M6PR and lysosomal enzymes are packaged into differently coated vesicles. The M6PR travels to late endosomes but then recycles to Golgi. M6PRs thereby avoid entering lysosomes.

A small amount of the M6PRs reside on the plasma membrane. Any M6P-tagged proteins that may be secreted instead of being delivered to lysosomes can bind to this cell surface M6PR and be delivered to lysosomes by this route. Interestingly, the cell surface cation-independent M6PR also acts as a receptor for insulin-like growth factor II (IGF-II). Binding of IGF-II to the cation-independent M6PR may be a mechanism for delivery of IGF-II to lysosomes. Alternatively, some aspects of IGF-II growth signaling may occur through the cation-independent M6PR.

There are indications that not all lysosomal matrix proteins are targeted to lysosomes by M6P. For example, in I-cell disease, there is a deficiency of the phosphotransferase enzyme, so no M6P can be formed on lysosomal enzymes. As expected, these cells accumulate degradative substrates within lysosomes owing to the deficiency of lysosomal hydrolases. However, lysosomes from some cell types from patients with I-cell disease have almost normal levels of many lysosomal enzymes. Such cells must have M6P-independent lysosomal targeting pathways.

2.2 Proteins in the Membrane

Lysosomal membrane proteins are also made from polysomes associated with the ER. They insert into the ER membrane because of a hydrophobic stretch of 22 to 26 amino acids within the protein sequence. These proteins contain critical amino acids in their cytosolic regions that direct their targeting to lysosomes (Fig. 2). The sequences are remarkably simple and consist of a tyrosine and a bulky hydrophobic amino acid that are present within the last four amino acids of the carboxy terminus. Alternatively, a leucine, typically in the form of a dileucine motif, can also target membrane proteins to lysosomes.

Heterotetrameric adaptor protein (AP) complexes, AP-1, AP-2, AP-3, and AP-4, will all bind tyrosine- or dileucine-based motifs. AP-1 is responsible for recycling of the M6PRs from endosomes to the Golgi. AP-2 is involved in clathrin-mediated internalization from the plasma membrane and is important for the internalization of secreted lysosomal enzymes. AP-3 is important for the intracellular biogenesis of lysosomes. AP-4 is localized to the Golgi and may also be involved in lysosome biogenesis.

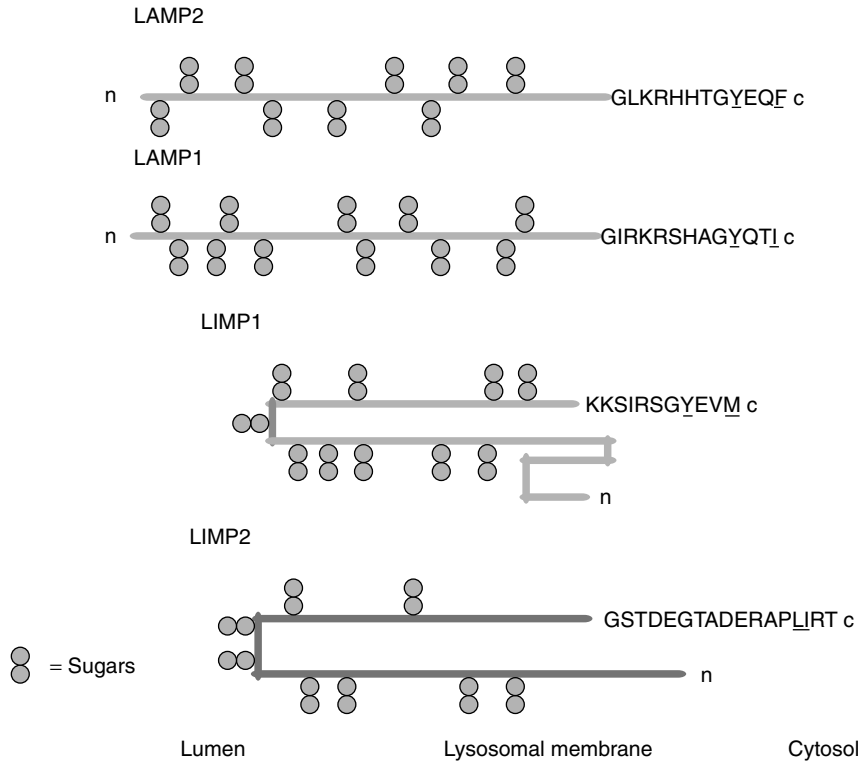

Fig. 2 Diagrammatic structures of integral lysosomal membrane proteins. n = amino terminus; c = carboxyl terminus. LAMPs and LIMPs are defined in the text. The amino acid sequences of the cytosolic tails are shown. Amino acids experimentally shown to be important in targeting the protein to the lysosomal membrane are underlined.

COPI coats also recognize both tyrosine-based and dileucine motifs. An additional family of proteins called Golgi-localizing, gamma adaptin ear homology domain, ARF-binding (GGAs) form vesicular coats and bind to dileucine motifs in the M6PRs. The GGAs are thought to participate in lysosomal biogenesis and/or trafficking of the M6PRs.

Rabs and SNAREs are also required for this vesicular transport. Rab7 is most important for the targeting of lysosomal enzymes to lysosomes while Rab9 is important for targeting the M6PRs from endosomes to the Golgi.

3 Biogenesis of the Yeast Vacuole

We have a more complete understanding of protein targeting to the yeast vacuole compared to the biogenesis of mammalian lysosomes in part because of the power of yeast genetics. The initial stages of protein synthesis and transport through the ER and Golgi, glycosylation of lysosomal enzymes, packaging the enzymes into vesicles, and docking and fusion of those vesicles are similar to processes described for mammalian cells.

3.1 Proteins in the Lumen

Targeting of vacuolar lumen proteins does not require M6P or any other glycosylation signal. The vacuolar targeting of carboxypeptidase Y (CPY) has been studied in detail. More than 50 vacuolar protein sorting (*Vps*) gene product mutations result in CPY missorting and abnormal vacuolar morphology. The proper sorting of CPY requires a linear peptide sequence in the amino-terminal propeptide of the protein. A CPY receptor, Vps10p, binds to this region of CPY in the Golgi and the complex trafficks to a prevacuole compartment called a *multivesicular body* (MVB) prior to entering the vacuole. The Vps10p recycles to the Golgi. Various t-SNAREs and v-SNAREs are required for vesicle fusion with the MVBs or for fusion of MVBs with the vacuole (Fig. 3).

Two vacuolar proteins, aminopeptidase I (API) and α-mannosidase, enter the vacuole independent of any *VPS* genes. They require gene products from the cytoplasm-to-vacuole targeting (Cvt) pathway, which has considerable overlap with genes required for macroautophagy (Fig. 3). Both pathways utilize double-membrane vesicles to initially sequester material. The Cvt pathway selectively sequesters API or α-mannosidase multimers while macroautophagy isolates cytoplasm including API and α-mannosidase. Macroautophagy is stimulated by carbon or nitrogen starvation and is discussed in Sect. 5.3.

3.2 Proteins in the Membrane

Another vacuolar protein sorting pathway for vacuolar membrane proteins bypasses the MVBs and targets Golgi-derived vesicles directly to the vacuole. Two proteins that are targeted to the vacuole as membrane proteins, alkaline phosphatase (ALP) and the t-SNARE, Vam3p, follow this pathway to the vacuole (Fig. 3). The yeast homolog of AP-3 coats the vesicles containing these vacuolar proteins, and the AP-3 appears to be recruited by tyrosine or dileucine peptide sequences in the cytoplasmic tails of ALP and Vam3p. Many *VPS* genes are common for the CPY and ALP pathways, but mutants in specific *VPS* genes selectively disrupt one pathway or the other.

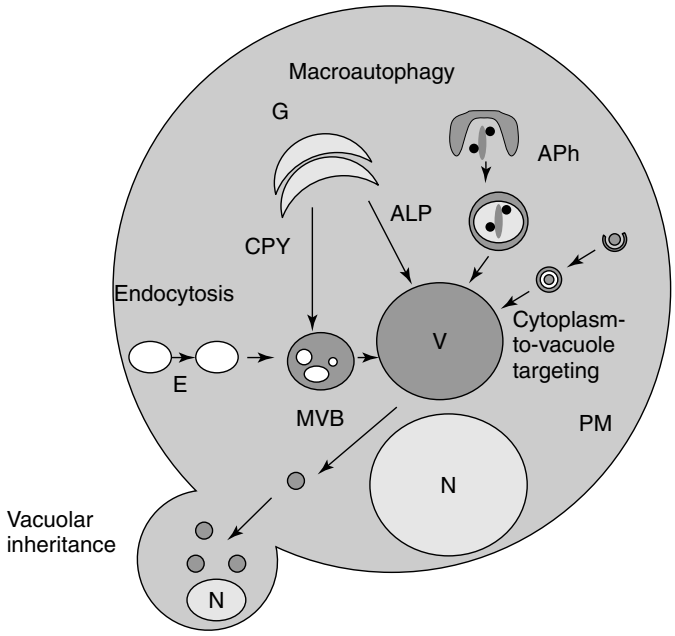

Fig. 3 Pathways for assembly of the vacuole in yeast. G = Golgi; APh = autophagosome; ALP = alkaline phosphatase; CPY = carboxypeptidase Y; E = endosome; MVB = multivesicular body; V = vacuole; PM = plasma membrane; N = nucleus. Pathways of vacuolar assembly and vacuolar inheritance are described in the text.

3.3
Vacuolar Inheritance

Vacuolar inheritance by daughter cells is initiated by a protrusion of the vacuole into the bud region. This protrusion vesiculates, and the vesicles move into the bud (Fig. 3). The vesicles eventually fuse to form the vacuole for the daughter cell.

4
The Importance of Phosphoinositides in Lysosomal Biogenesis

The lysosomal biogenesis pathways in mammalian cells and the vacuolar biogenesis pathways in yeast require phosphotidylinositol (PI) lipids. Phosphorylation of PI to phosphotidylinositol-3-phosphate (PI3P) can be inhibited by compounds such as wortmannin and 3-methyladenine. These inhibitors block lysosomal biogenesis and disrupt several different membrane trafficking processes. For example, both macroautophagy and endocytosis are inhibited by these compounds. PI3P acts at least in part by binding to proteins that are required for vesicular traffic. Some of these proteins contain Fab1, YGLO23, Vps27, EEA1 (FYVE) domains that bind PI3P. Different FYVE proteins are involved in different steps of vesicular traffic, docking, and fusion both in mammalian and in yeast cells.

5
Lysosomal Pathways of Proteolysis

There are several different pathways for intracellular protein degradation. The major pathway in the cytosol and nucleus is the ubiquitin/proteasome system. Other proteolytic systems in the cytosol include calpains and caspases. Most cells also exhibit a lysosomal component of proteolysis, and six different pathways of lysosomal proteolysis have been described in yeast (Fig. 4) and mammalian cells (Fig. 5).

5.1
Endocytosis

Extracellular proteins such as hormones, growth factors, and serum proteins can be internalized by receptor-mediated endocytosis, absorptive endocytosis, or fluid-phase endocytosis by both yeast (Fig. 4) and mammalian cells (Fig. 5). Proteins that are internalized by fluid-phase endocytosis do not interact with the plasma membrane. Proteins that adsorb to plasma membrane proteins or lipids or that bind to plasma membrane receptors can be internalized at rates hundreds or thousands of times more efficiently than by fluid-phase endocytosis alone.

Endosomes are usually coated by clathrin and AP-2 adaptor molecules. The clathrin is uncoated by the constitutively expressed hsp70 (hsc70), and the internalized material travels through early endosomes, late endosomes, and then to the vacuole (Fig. 4) or to lysosomes (Fig. 5) where they are degraded. In some cells, the degradation begins in early or late endosomes but is often completed within lysosomes.

The endocytic pathway can also deliver plasma membrane proteins to lysosomes for degradation (Figs 4 and 5). For example, the insulin receptor along with insulin is degraded within lysosomes. Other receptors may be spared lysosomal proteolysis because they are recycled to the plasma membrane. A growing number of plasma membrane proteins in yeast and mammalian cells are delivered to lysosomes for degradation only after a cytosolic domain has been tagged by ubiquitin.

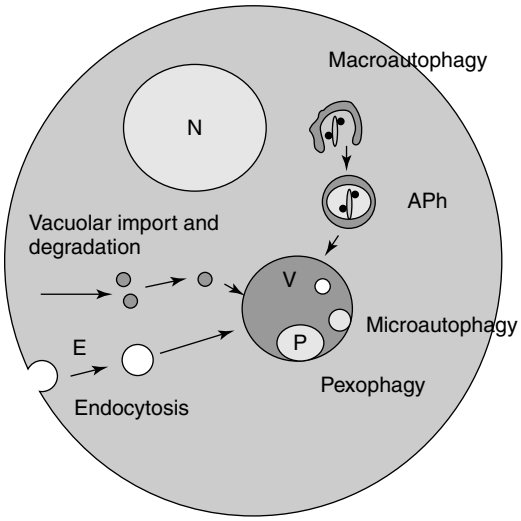

Fig. 4 Vacuolar pathways of protein degradation in yeast. N = nucleus; V = vacuole; APh = autophagosome; E = endosome; P = peroxisome. Four different pathways for vacuolar degradation of proteins, as listed in the figure and described in the text, have been described in yeast. Pexophagy refers to the microautophagic uptake of peroxisomes by the yeast vacuole.

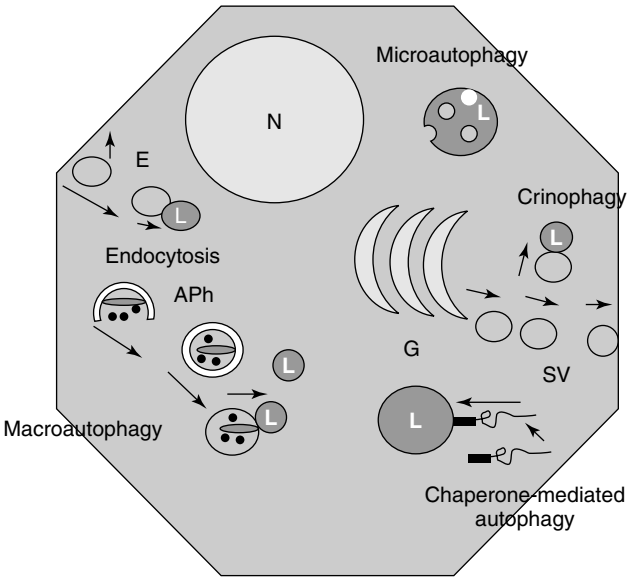

Fig. 5 Lysosomal pathways of protein degradation in mammalian cells. N = nucleus; L = lysosome; E = endosome; APh = autophagosome; G = Golgi; SV = secretory vesicle. Five different lysosomal degradation pathways in mammalian cells are listed in the figure and described in the text.

5.2 Exocytosis

Proteins can be secreted from mammalian cells by constitutive vesicular pathways or by regulated mechanisms in which the protein is stored in secretory vesicles (Fig. 5). When there is reduced physiological need for the secreted proteins, the secretory vesicles can fuse with lysosomes rather than the plasma membrane in a process called *crinophagy*. For example, when blood glucose levels are low, insulin secretion by the pancreatic islet β-cells is reduced. Under such conditions, the secretory vesicles containing insulin fuse with lysosomes and the packaged insulin is degraded. A percentage of serum albumin made by the liver and secreted constitutively is also degraded in this way. This degradation of secretory proteins has not been described in yeast.

5.3 Macroautophagy

Macroautophagy is a degradative pathway that is found in yeast (Fig. 4) and in mammalian cells (Fig. 5). Regions of the cytoplasm are sequestered in double-membrane vesicles called *autophagosomes* (APhs). The membranes surrounding APhs are lipid-rich and contain primarily a single protein. APhs often contain recognizable material such as mitochondria, peroxisomes, ribosomes, or glycogen. The APh acidifies, and then fuses with lysosomes after which the contents of the APh are digested.

Macroautophagy is induced in yeast because of nitrogen or carbon starvation and

in liver, kidney, and other tissues during fasting. The cause for the increased macroautophagy in mammalian tissues is a reduction in circulating amino acids combined with reduced insulin and elevated glucagon. Certain cancer cells are able to grow at least in part because they contain mutations that suppress macroautophagy.

Yeast mutants that fail to carry out macroautophagy under starvation conditions have been isolated and placed into approximately 20 complementation groups. These macro*a*uto*p*hagy (Apg) mutants result in the inhibition of different steps of macroautophagy including formation of APhs, growth of the APhs, docking and fusion with lysosomes, and digestion of the APh contents. The genes required for APh formation include a protein conjugation system reminiscent of ubiquitination. Apg12 is covalently linked to Apg5 through the actions of Apg10 and Apg7. Apg7 is a homolog of the ubiquitin activating protein, E1, and Apg10 is a homolog of a ubiquitin-conjugating protein, E2. Many of the yeast *APG* genes have homologs in mammals, so macroautophagic processes appear to be highly conserved.

Many *apg* mutants are also defective in the Cvt pathway used for delivery of API and α-mannosidase to the yeast vacuole. Other genes are unique for the Cvt pathway or for macroautophagy. For example, the Cvt19 protein acts as a receptor for API and α-mannosidase, and this protein is not required for macroautophagy.

5.4 Microautophagy

Microautophagy is the invagination of vacuolar membrane such that cytosol, organelles, or pieces of organelles are internalized within vesicles in the vacuole (Figs 4 and 5). Vacuolar lipases cause the break down of the internalized membrane. Microautophagy can also operate in modes that are selective for particular organelles such as peroxisomes or the nucleus. Microautophagy of peroxisomes (pexophagy) is stimulated when yeast is switched from methanol to glucose as an energy source (Fig. 4). A form of microautophagy called *piecemeal autophagy* of the nucleus is a constitutive process that is accelerated during starvation. It probably accounts for the degradation of nuclear preribosomal particles under conditions in which ribosome numbers in the cytosol decline. Microautophagy and macroautophagy have partially overlapping genetic requirements, but they also have distinct elements.

Microautophagy has been reproduced using isolated yeast vacuoles. The invagination of the vacuolar membrane requires ATP, GTP, and cytosol. In addition, a membrane potential across the vacuolar membrane is required.

5.5 Vacuolar Import and Degradation Pathway

Proteins such as fructose-1,6-bisphosphatase (FBPase) are synthesized in yeast when gluconeogenesis is required. These proteins are rapidly degraded within vacuoles in response to addition of glucose by a process called *vacuolar import and degradation* (Vid). FBPase may also be degraded by the ubiquitin/proteasome pathway. FBPase trafficking to the vacuole occurs in two steps: (1) import of the protein into an intermediate vesicle, the Vid vesicle, and (2) delivery of the Vid vesicle to the vacuole. The Vid vesicles are unique and contain one prominent membrane protein. Import of the protein into Vid vesicles requires hsc70 while delivery of the Vid vesicles to

the vacuole requires distinct t-SNAREs, v-SNAREs, and other membrane trafficking regulatory molecules.

Whether or not this pathway exists in mammalian cells is not yet known. It shares some mechanistic similarities with chaperone-mediated autophagy. Nevertheless, transport into vesicles prior to lysosome/vacuole delivery of the proteins remains a major difference in these two protein-degradation pathways.

5.6 Chaperone-mediated Autophagy

This lysosomal pathway of proteolysis is activated in liver and other mammalian tissues by prolonged starvation (Fig. 5). Macroautophagy is activated early in starvation but is subsequently suppressed when Cma is activated. In cultured fibroblasts and other cultured cells, macroautophagy is stimulated when cells reach confluence. Withdrawal of serum growth factors increases intracellular protein degradation due to Cma. However, other cell types in culture may stimulate macroautophagy and Cma simultaneously in response to withdrawal of growth factors.

Approximately 30% of cytosolic proteins are substrates for Cma. These proteins contain peptide-targeting sequences biochemically related to KFERQ. Examples of substrates of Cma include ribonuclease A, glyceraldehydes-3-phosphate dehydrogenase, cytosolic aspartate aminotransferase, aldolase B, and certain annexin isoforms, but not others. The KFERQ sequences are recognized by a complex of molecular chaperones including hsc70. The substrate protein-hsc70 molecular chaperone complex then binds to LAMP2a. The substrate protein is unfolded at the lysosomal surface presumably by the molecular chaperone complex prior to the protein's entry into the lysosome in a molecule-by-molecule process. The substrate protein's entry into lysosomes requires an intralysosomal form of hsc70 presumably to pull the substrate protein into the lysosome although the intralysosomal hsc70 may play other roles in Cma as well. The substrate protein is rapidly degraded in the lysosomal lumen.

6 Lysosomal Pathways of RNA Degradation

Lysosomes can also degrade RNA. Lysosomes are able to take up RNA, probably by macroautophagy since the RNA uptake by rat liver lysosomes increases in the absence of amino acids. It is interesting that glucagon also stimulates macroautophagy in the liver, but in this case protein, but little RNA, is delivered to lysosomes for degradation.

7 Lysosomal Storage Diseases

Mutations within genes encoding individual lysosomal enzymes can reduce their targeting to lysosomes and/or their activities within lysosomes. Such mutations result in the accumulation of materials within lysosomes, and identifying this stored material is often critical for identifying the missing enzyme activity (Table 1). For example, Tay-Sachs disease is associated with the lysosomal accumulation of particular gangliosides due to the absence of β-hexosaminidase. A more complicated lysosomal storage disease results from mutations in lysosomal cathepsin A. This peptidase cleaves a major protein of the

Tab. 1 Examples of lysosomal storage diseases.

Disease	*Enzyme deficiency*	*Stored material*
Tay-Sachs	β-Hexosaminidase	Gangliosides
α-Mannosidosis	α-Mannosidase	α-Mannose oligosaccharides
Sialidosis	Sialidase	Sialyl oligosaccharides
Farber	Ceramidase	Ceramide
Gaucher	Glucocerebrosidase	Glucoceramide
Niemann–Pick	Sphingomyelinase	Sphingomyelin
Hunter	Iduronate sulfatase	Heparin sulfate and dermatan sulfate
Galactosialidosis	Cathepsin A	Galactyl and sialyl oligosaccharides
I-cell	6-Phosphotransferase	Multiple substances

lysosomal membrane, LAMP2a. In addition, independent of its peptidase activity, cathepsin A protects two lysosomal glycosidases, β-D-galactosidase and *N*-acetyl-α-neuraminidase, from rapid intralysosomal destruction. In addition, cathepsin A is required for the proper lysosomal targeting of *N*-acetyl-α-neuraminidase. A defect in cathepsin A results in a combined deficiency of lysosomal activities of these two glycosidases and leads to the disease galactosialidosis.

9 Conclusions

Lysosomes are dynamic, multifunctional organelles. Lysosomal enzymatic content can be regulated under certain circumstances, but most control over the digestion of macromolecules is maintained by the sequestration of hydrolytic enzymes into membrane-bound organelles. Control of substrate delivery to the lysosomes appears to be the rate-limited process in these proteolytic pathways. Much less is known about delivery of nucleic acids and lipids for lysosomal degradation, but these topics are worthy of study.

Keywords

Chelate (from Greek claw)
Multiple bonding of two or more atoms of a single molecule to a metal ion, often to form five- or six-membered rings.

Ligand
A molecule or ion with a donor atom possessing a lone pair of electrons that interacts with a metal ion.

$pH = -\log(H^+)$
The negative decade logarithm of the hydrogen ion activity or concentration. Almost all chemists and biochemists calibrate a pH meter with buffers that yield a pH scale based closely on hydrogen ion activity. Many coordination chemists calibrate a pH meter using known concentrations of hydrogen ion. In the region of 0.1 to 0.2 ionic strength, the concentration scale yields acidity constant logarithms (pK_a values) about 0.12 log unit lower than those on the more common activity-based scale. Stability constants of metal ions with ligands are unaffected by the choice of pH scale.

Bioinorganic chemistry focuses on the roles played by noncarbon elements in life processes. Yet, bioinorganic chemistry is inseparable from the general chemistry of life. Carbon itself cycles among the many bioorganic compounds and inorganic carbon dioxide and carbonates. More than 80% of all the carbon in the earth's crust occurs as $CaCO_3$. About 30% of all enzymes contain metal ion cofactors. The most common metal ion, zinc, appears in over 100 enzymes; iron and copper, in a substantial number; manganese, cobalt, and molybdenum, in a few cases. Selenium appears in the enzyme glutathione peroxidase. Metal ions stabilize nucleic acid polymers, which bear a negative charge on each residue. Though blood is loaded with an array of organic molecules, its main constituent is NaCl and that of intracellular fluids is KCl. Even among the vitamins, a word coined from amines essential to life, the action of vitamin B_{12} depends upon a cobalt ion. Metal ions and nonmetals other than carbon are intimately and inseparably involved in life processes.

1 Essentiality

Twenty-one elements are essential to humans. An essential nutrient is one for which a deficiency results in an impairment of function that is relieved only by administration of that substance. Vitamins by definition and some minerals are essential. The significance of essentiality may be illustrated by burlesquing an old adage.

> "For want of a nail the shoe is lost, for want of a shoe the horse is lost, for want of a horse the rider is lost."
> George Herbert, *Jacula Prudentum* (Outlandish Proverbs), 1640

> "For want of a nutrient the enzyme is lost, for want of an enzyme the function is lost, for want of a function the life is lost."
> Bruce Martin, *Summa Veritatis* (Lofty Truth), 1989

Four essential elements H, O, C, and N comprise more than 99 atom % and about 96 wt % of the human body. These 4 and 14 other essential elements occur among the first 30 elements (through zinc) of the periodic table. Three heavier trace elements Se, Mo, and I are also essential in humans. For 17 tabulated essential elements, Table 1 shows the predominant elemental form at pH 7, typical adult concentrations in the blood plasma or serum, the approximate amount found in a 70 kg adult, and a recommended adult daily allowance. In addition to the four basic elements, the essential elements include two alkali metal ions, two alkaline earth metal ions, seven transition metals (the most common, iron, contributes to less than 0.01% of body weight), phosphorus, sulfur, selenium, and three halogens. Table 1 shows that most of the remaining 4% of body weight consists of 2 elements found in bone, Ca and P. Many of the elements do not exist predominantly in their pH 7 forms in the serum as they are combined with other components. For example, Fe^{3+} does not precipitate as the hydroxide but is retained by tightly chelating ligands. There is little free iodide; it occurs as part of the thyroid hormones. For sulfur, Table 1 lists the total serum concentration, most of which appears in proteins; there is only about 1 mM nonprotein sulfur. Sulfur is not

Tab. 1 Essential elements in humans.[a]

Element	*pH 7 form*	*Serum conc.*	*Human amt.*	*Daily allowance*
Na	Na^+	140 mM	70 g	1–2 g
K	K^+	4 mM	130 g	2–5 g

mM concentrations	*Extracellular*	*Intracellular*
Na^+	140	10
K^+	4	140
Ca^{2+}	2	0.0001
Mg^{2+}	1	1
Cl^-	104	4
HCO_3^-	27	10
HPO_4^{2-} & $H_2PO_4^-$	1	10
SO_4^{2-}	1	7
pH	7.4	6.6

important as an inorganic element but only as part of the amino acids cysteine and essential methionine. An additional four elements, B, Si, V, and Ni, not included in Table 1, are essential for other organisms.

Table 2 shows the concentrations of several ions in the blood plasma and in a typical intracellular fluid. While the concentration of Mg^{2+} is similar on both sides of the cell membrane, the concentration of K^+ is greater on the inside and those of Na^+ and Ca^{2+} are greater on the outside of a cell. A pump, driven by the protein Ca-ATPase, maintains the 20 000-fold concentration difference for Ca^{2+}. These concentration differences illustrate how compartmentalization in biology leads

to differences in concentration from a surrounding milieu.

Essentiality is not the only criterion for inclusion of elements in a survey of bioinorganic chemistry. Organisms may accumulate elements without their being essential. Some elements such as arsenic and antimony have been used therapeutically, and bismuth still is. Others such as Al and the heavy metals Cd, Hg, Tl, and Pb are toxic and prevalent, and their interactions with life processes are of concern.

2 Abundances

In the natural environment, most essential elements are relatively abundant and most toxic elements are relatively rare. Abundant crustal elements that have not become essential, such as Si, Al, and Ti, are not easily accessible. Life evidently evolved by using elements that are not only abundant but also accessible and suitable. Some relatively common elements are not used in living organisms because similar roles are played by more common elements; Cl is 10^3 times more abundant than Br, Ca is 100 times more abundant than Sr, and Na and Mg are both 100 times more abundant than Li. Boron, the 11th-ranking element in oceans, is essential for some plants but not animals. Essential Mo, I, and Se do not even occur in the upper 50th percentile in crustal atom abundance, but Mo ranks 20th in abundance in the oceans and is the most abundant transition metal ion in seawater.

Of the most toxic elements – arsenic (As), cadmium (Cd), mercury (Hg), thallium (Tl), and lead (Pb) – only the last occurs in the upper 50th percentile in the crust, and As and Cd occur similarly in the oceans. Thus, the most toxic elements are much rarer on the whole than the essential elements. However, both in the crust and in the oceans essential Mo and toxic As appear in comparable amounts as do essential Se and toxic Cd.

3 Ionic Radii

Like size usually plays a greater role than identical charge in promoting metal ion substitutions in biology. Table 3 presents effective ionic radii for many metal ions. For any metal ion, the radius increases with coordination number, since the greater number of bonds weakens the strength of any one bond. The radius of the most common coordination number is underlined in Table 3. The alkali and alkaline earth metal ions exhibit variable coordination numbers without strong directionality in bonding. Because they are of similar size, Ca^{2+} and Na^{+} of differing charges often interchange in biological systems. Ba^{2+} is poisonous because of its antagonism to K^{+} of similar radius and not to Ca^{2+} of identical charge but smaller radius. Ba^{2+} is a muscle poison for which one antidote is intravenous infusion of K^{+}.

4 Ca^{2+} Versus Mg^{2+}

To many, there are insufficient fundamental differences between the pair of alkaline earth metal ions Ca^{2+} and Mg^{2+} to explain their widely differing roles in biology. There are, however, ample ways to account for the behavior differences between Ca^{2+} and Mg^{2+} observed in biochemical systems.

Tab. 3 Effective ionic radii in picometers.

Ion	*Coordination number*[a]					
	4	*5*	*6*	*7*	*8*	*9*
Be^{2+}	27		45

Rb^{+}			152	156	161	163
Cs^{+}			167		174	178

[a] Radius of the most common coordination number is underscored.
[b] High spin; low-spin value is 55.
[c] High spin; low-spin value is 61.

1. Ca^{2+} favors a higher-fold coordination number than Mg^{2+}. The favored coordination number for Mg^{2+} is sixfold octahedral. Ca^{2+} exhibits a greater diversity of coordination numbers, with eight- and sixfold coordination being the most common with small ligands. Since coordination in both metal ions is mainly ionic, the greater coordination numbers for Ca^{2+} derive ultimately from its larger size.
2. Ca^{2+} is substantially larger than Mg^{2+}. In the same coordination number, the effective ionic radii of Ca^{2+} are at least 23 pm greater than those of Mg^{2+} (Table 1.) If the most favored coordination numbers are considered, Ca^{2+} (eightfold) possesses a 40 pm greater effective ionic radius than Mg^{2+} (sixfold).
3. Ca^{2+} to ligand donor atom bond distances vary more than those of Mg^{2+}. Bond distances to oxygen donor atoms typically range from only 20 to 21 pm for Mg^{2+} and a broader 23 to 26 pm for Ca^{2+}. Thus, Mg^{2+} prefers to form

well-defined six-coordinate octahedral complexes with precise bond lengths and Ca^{2+} forms looser complexes of higher and more variable coordination number, without directionality and with variable bond lengths.

4. Though both ions favor coordination at oxygen donor ligands, Mg^{2+} binds more strongly than Ca^{2+} to small ligands with nitrogen donors. With respect to the pair of related tridentate ligands oxydiacetate and iminodiacetate, Ca^{2+} binds more strongly to the former and Mg^{2+} to the latter N-donor ligand. The stability constant for Mg^{2+} binding is greater for iminodiacetate than for oxydiacetate, while for Ca^{2+} the reverse is true. Mg^{2+} binds to four nitrogen donors in chlorophyll, while Ca^{2+} does not.
5. Ca^{2+} is more comfortable than Mg^{2+} in binding to large, multidentate, anionic ligands. Although Mg^{2+} binds more strongly than Ca^{2+} to iminodiacetate, Ca^{2+} binds more strongly to nitrilotriacetate, EGTA, and EDTA. Ca^{2+} binds to EGTA a striking $10^{5.6}$ times more strongly than does Mg^{2+}. In all three ligands, there are steric requirements that the larger Ca^{2+} fulfills better than Mg^{2+}. Mg^{2+} binds slightly more strongly to nucleoside phosphates,, but within cells, there is insufficient free Ca^{2+} for binding. Within cells, Mg^{2+} associates with phosphates and Ca^{2+} binds tightly to proteins.
   The equilibrium picture shows Mg^{2+} forming more restrictive complexes, usually hexacoordinate with precise bond lengths, favoring smaller chelate groupings, and more readily accepting nitrogen donors. In contrast, Ca^{2+} forms less well-defined complexes with eight-, six-, and other fold coordination with variable bond lengths and favors larger multidentate anionic ligands. These equilibrium stability and structural differences account for differentiation between Ca^{2+} and Mg^{2+} in biological systems.
6. Ca^{2+} undergoes substitution at least 10^3 times faster than Mg^{2+}. The slower rate for Mg^{2+} probably results from a more limited capability to aid substitution by reducing or enlarging its coordination sphere. Thus, from both static and dynamic viewpoints, Mg^{2+} forms the more prescribed and tighter complexes.
7. Insolubilities of their common phosphate salts provide only a weak differentiation between Mg^{2+} and Ca^{2+}. Inorganic Mg^{2+} phosphates are up to 10 times more soluble than Ca^{2+} salts of similar structure. Both metal ions form soluble salts with organic phosphates. The main difference between Mg^{2+} and Ca^{2+} is that, owing to its small size, Mg^{2+} fails to form a structure like the most insoluble of the Ca^{2+} phosphates, hydroxyapatite, $Ca_5(PO_4)_3OH$.

5 Stability Sequences

From the many studies on stability constants, one finds the order of metal ion stabilities to be dependent on the ligand. Increasing metal ion stabilities follow the orders

Glycine:
Ca, Mg $\ll$ Mn $<$ Fe, Cd, Pb $<$ Co,
Zn $<$ Ni $\ll$ CH_3Hg^+, Cu $\ll$ Hg
1,2-Diaminoethane:
Mg $\ll$ Mn $\ll$ Fe $<$ Pb, Cd, Co, Zn $\ll$
Ni $<$ CH_3Hg^+ $\ll$ Cu $\lll$ Hg

The ion Ca^{2+} does not form stable amine complexes. Except for methyl mercury,

CH_3Hg^+, all the metal ions carry two positive charges. Owing to the strongly chelating bidentate ligands, glycine (gly) and 1,2-diaminoethane (en), CH_3Hg^+ with only a single strong binding site is at a competitive disadvantage in the above series. To a unidentate ligand, CH_3Hg^+ binds more strongly than all of the above metal ions except Hg^{2+}.

In the above series, each inequality sign stands for an approximate 10-fold increase in stability constant. The two series gly and en are similar, their major difference being a stability constant span from Mg^{2+} to Hg^{2+} of 10^9 for glycine and 10^{14} for en. Generally, the increment between metal ions increases on passing from O < N < S donor atoms. The presence of a sulfur donor promotes Cd^{2+} and Pb^{2+} to higher positions than that in the above series. The order of increasing sulfur-binding strengths is $Zn^{2+} < Cd^{2+} < Pb^{2+} < CH_3Hg^+ < Hg^{2+}$. Sulfhydryl group interactions are the main mode of toxicity of the heavy-metal ions. These general bonding features are expressed in the concept of the stability ruler.

6 Stability Ruler

For a single ligand, the Irving–Williams stability sequence of dipositive metal ions is Mg < Mn < Fe < Co < Ni < Cu > Zn, invariant of ligand. The uniformly progressive part of this sequence from Mg^{2+} to Cu^{2+} defines a *stability ruler* to which more variable metal ions may be compared. The stability ruler appears across the top of Table 4. For several ligand donor sets, Table 4 shows the relative binding strengths of the variable dipositive metal ions Zn^{2+}, Cd^{2+}, Pb^{2+}, and Hg^{2+}. Their placement in Table 4 corresponds to their stability constants compared with those of the metal ions that define the ruler. The entries for glycine and en agree with the series in the previous section. With most of the metal ions in Table 4, histidine will be tridentate. The increment between metal ions and hence the length of the stability ruler increases with the substitutions O < N < S. The ruler length appears in the second to last column of Table 4 in log*K* units for binding to each ligand. The longer the ruler, the more discriminating

Tab. 4 Stability ruler.[a]

Ligand	*Donors*	*Mg*	<	*Mn*	<	*Fe*	<	*Co*	<	*Ni*	<	*Cu*	*Length*[b]	*Hg*[c]
Hydroxide	OH^-				Cd						Zn	Pb	3.7	1.2
Acetate	O^-									Zn	Cd	Pb	1.3	1.2
Imidazole	=N							Zn	Cd				4.0	1.1
Ammonia	NH_3						Pb		Zn	Cd			4.0	1.1
Oxalate	O^-,O^-				Cd			Zn	Pb				2.1	
Glycine	N,O^-					Cd	Pb	Zn					6.1	0.4
Histidine	N,=N					Cd	Pb	Zn					8.2	0.2
$NH_2(CH)_2NH_2$	N,N					Pb	Cd	Zn					10.1	0.4
$NH_2(CH)_2S^-$	N,S^-									Zn	Cd	Pb	12(est.)	0.2

[a] All dipositive cations.
[b] Ruler length in difference between log stability constants of Cu^{2+} and Mg^{2+} complexes.
[c] Relative magnitude that the Mg^{2+} to Cu^{2+} length must be extended to reach the Hg^{2+} value.

the ligand in selecting among metal ions. Thus, ligands with oxygen donor atoms are least discriminating among metal ions, nitrogen donors intermediate, and sulfur donors most discriminating.

Not only do Co^{2+} and Zn^{2+} display nearly identical radii for the same coordination number in Table 3 but they also exhibit similar stabilities for all ligands in Table 4, except for those involving sulfur and hydroxide. The similarities allow the facile and useful substitution of Co^{2+} for Zn^{2+} in many enzymes. When a sulfhydryl group is present, as in 2-mercaptoethylamine, Zn^{2+} binding strengthens, equaling that for Ni^{2+}. Table 4 also shows the relative strengthening of Cd^{2+} and Pb^{2+} binding with the sulfhydryl donor in 2-mercaptoethylamine.

To most unidentate ligands, Cd^{2+} binds more strongly than Zn^{2+}. Probably because of an unfavorable ring bite size for the relatively large Cd^{2+} (Table 3), Zn^{2+} chelates more strongly to ligands containing O and N donors. Table 2 shows that upon introduction of an S donor atom into a chelate, Cd^{2+} becomes the stronger metal ion binder.

For all donor sets in Table 4, Hg^{2+} binds so strongly that it is off the end of the ruler scale. The number under Hg in the last column of Table 4 refers to the relative distance by which the length of the whole log stability-constant scale from Mg^{2+} to Cu^{2+} must be extended to reach the value for Hg^{2+}. A telling contrast appears between the length of the extension for most bidentate compared to unidentate ligands. The scale extension for Hg^{2+} amounts to 0.2 to 0.4 log units for bidentate ligands and to 1.1 to 1.2 log units for the 3 unidentate ligands at the end of Table 4. The difference arises because Hg^{2+} prefers linear two-coordination and binds the second donor atom in small chelate rings much more weakly than the first donor atom.

We may generalize the results and conclusions of the stability ruler by noting that alkali metal and alkaline earth metal ions, lanthanides, and Al^{3+} prefer oxygen donors; transition metal ions, oxygen and nitrogen donors; and the heavy-metal ions, nitrogen and sulfur donors.

7 Metal-ion Hydrolysis

The higher the charge density or charge-to-radius ratio, the more likely it is for a metal ion to undergo hydrolysis in aqueous solutions to form hydroxo complexes. Hydroxo complexes may abruptly form polynuclear complexes and precipitate even in solutions more acidic than the pK_a for first hydroxo complex formation. The first five small metal ions in Table 3 hydrolyze even in acidic solutions and form precipitates. In six coordination, the charge-to-radius ratio for the first five metal ions is greater than 0.044, while for all the other metal ions in Table 3, the ratio is less than 0.035. The first five metal ions cannot occur to an appreciable extent in the bloodstream (pH 7.4) as the free aqueous ion and must be complexed in some way. Covalence may also promote complex formation and hydrolysis in acidic solutions, as is the case for Hg^{2+}.

Hydroxo complex formation follows the same stability order as other ligands with the strongest binding at the right of the stability ruler in Table 4, where the hydroxide ion appears as the first entry. The stability ruler in Table 4 shows that Zn^{2+} and Pb^{2+} exhibit relatively strong tendencies to form hydroxo complexes and precipitates.

8
Hard and Soft Acids and Bases

8.1
Definitions

More than 45 years ago, metal ions were divided into two groups: a majority labeled class (a) for which the anion-binding strength in aqueous solutions is greatest for F^- and generally follows the order $F > Cl > Br > I$, and a minority class (b) in which F^- binding is weaker than at least one of the heavier anions and generally follows the order $F < Cl < Br < I$ (in the gas phase, all metal ions follow the first order). The same trends occur in other columns in the periodic table; for example, class (a) metal ions tend to favor binding to oxygen and class (b) metal ions to sulfur ligands. Subsequently, Pearson extended the application and changed the terminology so that class (b) metal ions became soft and class (a) metal ions were subdivided into hard and borderline groups. The greater popularity of the altered nomenclature is partly because it is easier to say harder or softer than more (a) character or more (b) character. Thus, it is now said that fluoride and chloride are hard, bromide is borderline, and iodide is soft.

The dictum by Pearson that hard acids prefer to interact with hard bases and soft acids with soft bases has become well known. In biochemistry, there are only four main types of ligand donor atoms, of which O and aliphatic N are classified as hard, aromatic N as borderline, and S as soft bases. All alkali, alkaline earth, and lanthanide ions are classified as hard, as are the first five metal ions in Table 3 and Mn^{2+}. Borderline metal ions include the last four of the stability ruler (Table 4) and Zn^{2+} and Pb^{2+}. Soft metal ions include Ag^+, Cd^{2+}, CH_3Hg^+, and Hg^{2+}.

Despite the popularity of the hard–soft designation, there was a lapse of a quarter century before Pearson proposed a quantitative scale. Pearson defined softness as the reciprocal of hardness and presented quantitative absolute hardness values for metal ions and ligands (in which the hardness of an atom and an anion such as F and F^- are identical). A few years later, Pearson disavowed his quantitative hardness scales for at least some cations and anions. In any case, the hardness values for metal ions do not correlate at all with the stability constants of complexes, which are correlated best by the electron affinity of the metal ion. Though often spoken of by chemists as if it is the determining factor in complex stability, the contribution of hardness or softness may pale when compared to the intrinsic stability, which often dominates the binding strength.

8.2
Substitution Reactions

Comparisons of hardness and softness, like the stability order of halide complexes mentioned in the first paragraph, are equivalent to describing the extent of substitution (not exchange) reactions. We quantitatively evaluate the free energy change in the form of log stability-constant differences of substitution reactions. If M and N are two different metal ions and X and Y two different ligands, we may compare the hardness of a metal ion by considering the substitution on the metal ion of one ligand by another

$$MX + Y \rightleftharpoons X + MY$$

for which the free energy change is proportional to $\log K_{MY} - \log K_{MX}$, where K_{MY} and K_{MX} are the stability constants for complexes MY and MX respectively.

An advantage of such a comparison is that it greatly reduces the overlooked effect of a reduction in coordination number from the aqueous ion for several soft metal ions in augmenting stability constants by powers of ten. Similarly, we may compare the hardness of a ligand by considering the substitution on the ligand of one metal ion for another

$$MX + N \rightleftharpoons M + NX$$

for which the free energy change is proportional to $\log K_{NX} - \log K_{MX}$. By considering such substitution reactions, one gains consistency in application of the principle of hard and soft acids and bases. The scales presented are practical scales dependent only upon experimental stability constants determined in aqueous solutions, and they do not involve any other quantities such as electron affinities and other parameters from gas-phase reactions, heats of hydration, or heats of reaction. Nor do the scales presented assume a model or rely on derived parameters with arbitrary scaling. The practical scales probably represent what most investigators imply when they make comparisons using the terms *hardness* and *softness*.

8.3 Metal-ion Scales

Of two scales involving oxygen and nitrogen donors hydroxide–ammonia and acetate–ammonia, only the latter is described here. As an oxygen donor ligand, hydroxide may not be typical (see below), and for applications acetate may offer a more representative oxygen donor ligand than hydroxide. Acetate–ammonia stability-constant log differences for 22 metal ions and the proton are ordered in the following acetate–ammonia (O–N) scale, with the differences in parentheses. The scale spans 8.0 log units and each of the 8 greater than signs indicates a factor of near 10. Pearson's hard metal ions appear in normal type, borderline in bold, and soft in italics.

Sc(2.8) > La(1.6), Ce(1.5), Y(1.3), Lu(1.2) > *Tl(I)*(0.8), Ca(0.7), Li(0.6), **Pb**(0.6), Mg(0.3) > Fe(III)(−0.4), Mn(−0.4), In(−0.5) > **Co**(−1.0), *Cd*(−1.1), **Zn**(−1.2) > **Ni**(−2.0), **Cu**(−2.3) > *Ag*(−2.9), *Tl(III)*(−2.9) > CH_3Hg^+(−4.1), H^+ (−4.5) > *Hg*(−5.2).

O–N scale

Metal ions favoring acetate appear at the beginning of the O–N scale and those favoring ammonia at the end. Of the first 13 metal ions, 11 are hard, but in this group there is 1 soft (Tl^+) and 1 borderline (Pb^{2+}) metal ion. Next, a group of 4 borderline metal ions also contains 1 soft metal ion (Cd^{2+}). The scale ends with four soft metal ions but also with the hard proton.

Unfortunately, it is impossible to develop a comparable hardness scale with unidentate sulfur donor ligands as very few reliable experimentally determined stability constants are available. Polymerization has gone unrecognized in many of the determinations. Many of the constants involve chelate rings that introduce the additional variable of chelate ring bite size with metal ions of varying radii. Ag^+ and Hg^{2+} prefer linear coordination making formation of five- and even six-membered chelate rings highly strained. For this reason, unidentate ligands are the focus of this article.

By relaxing the requirement for unidentate ligands, we may compare the tendency of some metal ions to bind

to oxygen or sulfhydryl donor atoms. Stability constants have been tabulated for binding to substituted iminodiacetates, $R-N(CH_2COO^-)_2$. For $R = -CH_2COO^-$ (nitrilotriacetate) and $R = -CH_2CH_2S^-$, the difference in stability-constant logs for the former minus the latter tridentate ligand is given in parentheses, in sequence, after each dipositive metal ion.

Ca(1.5), Sr(1.4), Ba(1.3), Mg(1.1)
≫ Mn(−1.9), **Ni**(−2.2), **Fe**(−2.9)
≫**Zn**(−5.3), **Pb**(−5.6), *Cd*(−6.9),
Hg(<−8).

O−S scale

Similar differences and sequences are obtained with $R = -CH_2CH_2OH$ as the oxygen donor, with the addition of poorly chelating Hg^{2+}, still with the greatest negative value. Metal ions in the O−S scale fall distinctly into three groups: alkaline earths with differences from +1.5 to +1.1, transition metal ions from −1.9 to −2.9, and filled d-orbital ions from −5.3 to <−8. The spans within the first two groups are narrower than the gaps between the three groups. For oxygen−sulfhydryl binding, the alkaline earths may be designated as hard, the three transition metal ions as borderline, and the four filled d-shell metal ions as soft. The recognized avidity of Zn^{2+} for sulfhydryl donors is confirmed. Though assigned as hard by Pearson, by this grouping Mn^{2+} is emphatically borderline. This borderline designation for Mn^{2+} is also more consistent with other scales.

8.4 Ligand Scale

We now create a ligand scale, corresponding to the second substitution reaction of Sect. 8.2, by considering the differences between stability-constant logarithms for soft and hard metal ions for several ligands. Hg^{2+} stands as the preeminent soft metal ion. Sc^{3+} is the hardest metal ion in several scales, but results are limited. More ligands may be included if results for the smaller and heavier lanthanides are considered for the hard metal ion. For 16 ligands, the difference between the stability-constant logarithms for Hg^{2+} minus a lanthanide in parentheses is as follows:

F^-(−3), H_2O(0), acetate(2),
HCO_3^-(4), CO_3^{2-}(5),
OH^-(5) > **pyridine**(6),
benzimidazole(6), **imidazole**(7),
Cl^-(7), NH_3(8), SCN^-(9),
Br^-(9) > I^-(13), CN^-(13),
$S_2O_3^{2-}$ (14).

Ligand scale

Ligands assigned by Pearson as hard appear in normal type, borderline in bold, and soft in italics. For Pearson, aliphatic amines are hard and aromatic amines are borderline. Since imidazole binds metal ions through a borderline pyridine-type nitrogen, imidazole is also classed as borderline in the ligand scale. Use of CH_3Hg^+ in place of Hg^{2+} yields a virtually identical ordering with a lesser span of 13 log units.

The hardest ligands appear at the beginning of the ligand scale, which spans 17 log units. Cyanide and thiocyanate are ambivalent ligands; virtually all metal ions bind to CN^- through the carbon atom. Even upon binding the first CN^-; Cu^+, Ag^+, and Hg^{2+} undergo a reduction to two-coordination. A reduction to four-coordination occurs upon binding of the second CN^- to Ni^{2+} and Zn^{2+}. A reduction in coordination number strengthens binding.

The above order of increasing softness of the amines is also the order of increasing basicity. The influence of greater basicity in yielding increasing softness is also illustrated by two other comparisons in the ligand scale: $H_2O(0) < OH^-(5)$ and $HCO_3^-(4) < CO_3^{2-}(5)$. These sequences point a general feature of metal ion stabilities: greater basicity yields greater metal ion stability, which in turn provides greater discrimination among metal ions, which in turn gives rise to softness. Often, however, other factors overwhelm the influence of basicity: among the halides, fluoride is both the strongest base and the hardest.

In the ligand scale, the relative softness of the presumably hard ammonia(8), comparable to borderline bromide(9) and soft thiocyanate(9), emerged unexpectedly. The above ligand scale serves as a quantitative indication of the relative hardness of ligands. The 2 inequality signs divide the 16 members of the ligand scale into 3 groups on the basis of the magnitude of the differences. The first 6 ligands are assigned as hard by Pearson; of the next closely spaced 7 ligands, 2 are hard, 4 borderline, and 1 soft. The ligand scale ends with 3 soft ligands. On the basis of the quantitative results of the ligand scale, previously hard ammonia and chloride and soft thiocyanate are more appropriately switched into the borderline group. These switches more consistently place all amines, aliphatic and aromatic, in the same borderline group. The recommended designations lead to a consistent sequence of 6 hard, 7 borderline, and 3 soft ligands. Thus, all oxygen donor ligands are designated hard and all nitrogen donors borderline. Within the borderline group, aliphatic amines are softer than aromatic amines.

8.5 Lead

Lead (Pb^{2+}) presents a case that demonstrates limitations in the hard–soft concept. The first stability-constant logarithms for lead and the halide ions, all at 25 °C and 1.0 M ionic strength, appear in parentheses: F(1.44) > Cl(0.90) < Br(1.10) < I(1.26). The increasing trend for the last three halides describes class (b) behavior, while the greatest value for F^- characterizes a class (a) metal ion. Pb^{2+} interacts relatively strongly with both oxygen (hard) and sulfur (soft) donor ligands, and relatively weakly with nitrogen donor ligands, as illustrated in the stability ruler. Despite the presence of a free sulfhydryl group on the proteins, Pb^{2+} binding occurs exclusively at the Ca^{2+} sites (composed solely of O donors) of oncomodulin and chick vitamin D–induced intestinal calcium-binding protein. Pb^{2+} also combines with the components of nucleic acids. In many examples, Pb^{2+} eschews borderline (is antiborderline) and opts for either hard or soft behavior, making the simple hard–soft concept ineffective for use with this metal ion. In contrast, compared to other metal ions, Ni^{2+} exhibits a tendency to prefer nitrogen over oxygen or sulfur donors (except when two or more sulfur donors promote a diamagnetic complex of reduced coordination number). The position of the proton swings from one end to another of the several metal ion scales. Much more than Pb^{2+}, the proton displays strong antiborderline behavior appearing at either the hard or the soft ends of the scales. Thus, biology offers metal ion environments inconsistent with and unpredictable under

the hard and soft classification scheme. In another example, in the iron–sulfur protein rubredoxin, sulfur exclusively (soft) coordinates to both Fe^{2+} (borderline) and Fe^{3+} (hard).

8.6 Conclusions

Note again that the numerical values associated with hardness–softness in this article are based wholly on experimentally determined log stability-constant values determined in aqueous solutions at room temperature. The values are not absolute; addition of more metal ions might extend the scales in either direction. Small differences between metal ions should not be over-interpreted. The relative difference scales are linear in log stability constant, stretching from very hard at one end to very soft at the other. As hardness decreases, softness correspondingly increases, and vice versa. These practical scales are not comparable to that of Pearson, where absolute hardness values are derived from gas-phase parameters, and softness is the reciprocal of hardness.

In practice, the principle of hard and soft acids and bases is often contorted in such a way as to provide nonfalsifiable explanations for almost any observation. The limitations of the principle need greater exposure. The very hard Sc^{3+} and the very soft CH_3Hg^+ both bind strongly and nearly equally to the hard ligands hydroxide on one hand and acetate on the other (Table 1). Though both metal ions are considered as very soft, Hg^{2+} is among the strongest binders to hydroxide and acetate, and Ag^+ among the weakest. Many other such anomalies may be found by considering differences of stability-constant logs. It is only when these differences are compared that one finds some quantitative justification for the principle of hard and soft acids and bases. The principle of hard and soft acids and bases finds its most consistent application not in direct stability-constant comparisons but rather in the free energy or log stability-constant differences of the substitution reactions of Sect. 8.2.

9 Nonaqueous Environments

Nonaqueous solvents that lower the dielectric constant increase stability constants between oppositely charged ions, decrease the constants between identically charged ions, and leave relatively unaffected stabilities with one neutral reactant species. For example, on passing from water to a mixed solvent system containing 70% by weight dioxane, the dielectric constant drops from 79 to 18. This solvent change increases the pK_a of acetic acid by 3.6 log units and decreases the pK_a of anilinium ion by 1.0 log unit. The much larger change in the former case is due to the reaction between oppositely charged proton and acetate becoming much more favored in the lower dielectric medium. In contrast, the latter reaction is merely transfer of a proton from water to amine without the creation or destruction of any charges.

Binding sites in proteins display lower dielectric constants than the surrounding water. An equivalent solution dielectric constant applicable to binding sites in metalloproteins is calibrated with metal ion stabilities in nonaqueous solvent mixtures. For the zinc ion active sites in bovine carbonic anhydrase and carboxypeptidase A, the equivalent solution dielectric constants are estimated as 35 and 70 respectively. The former enzyme reacts with a smaller

substrate and possesses a much less open binding site.

10 Other Factors

Numerous other factors affect metal ion affinities including size and number of chelate rings, presence of other ligands, noncovalent interactions among ligands, ligand field strength (at most 10% of total binding energy), and spin state (important in heme proteins).

11 pH-dependent Stabilities

If at a given pH a ligand occurs in a protonated form, competition develops between metal ion and proton for a basic ligand site. The concentration of basic ligand available to the metal ion drops in the presence of protonated ligand species. Neutral solutions contain ligands with protonated amine, phenolic, and sulfhydryl groups. In these and other cases, the tabulated stability constants overstate the effective binding strength, and its magnitude needs to be reduced to reflect competition from the proton.

The tabulated stability constant K_s refers to the following equilibrium:

$$M + L \longrightarrow ML \quad K_s = \frac{[ML]}{([M][L])}$$

With a protonated ligand, however, the relevant formation reaction becomes $M + HL \rightarrow ML + H^+$. There is the additional acid–base equilibrium of the ligand.

$$HL \longrightarrow H^+ + L \quad K_a = \frac{(H^+)[L]}{[HL]}$$

The fraction of the ligand in the basic form available for metal ion binding is given by

$$\alpha = \frac{[L]}{([HL] + [L])} = \frac{K_a}{[(H^+) + K_a]} \text{ so that}$$
$$0 < \alpha < 1.$$

The conditional, pH-dependent stability constant is given by $K_c = \alpha K_s$, or

$$\log K_c = \log K_s - pK_a - \log[(H^+) + K_a]$$

For $pH \gg pK_a$, as for carboxylates in neutral solutions, the basic form of the unbound ligand predominates and $\log K_c = \log K_s$. For $pH \ll pK_a$, as for aliphatic amines in neutral solutions, the unbound ligand is predominantly protonated and $\log K_c = \log K_s - pK_a + pH$, and the conditional constant shows a pH dependence. When the pH is within 1.5 log units of pK_a, the complete equation should be used. By allowing for withdrawal of deprotonated ligand from solution by protonation, the value of the conditional stability constant becomes less than the standard stability constant, $K_c \leq K_s$. (The conditional constant may exceed the tabulated constant for cases in which a subsequent deprotonation occurs from a complex.)

In Table 5, conditional stability constants at pH 7.0 (represented as K_7) are compared with the tabulated stability constants (K_s) for three metal ions and four unidentate ligands. The four ligands represent carboxylate, imidazole, sulfhydryl, and aliphatic amine donors in biological systems. For acetate, $pH = 7 \gg pK_a$, $\alpha = 1$, virtually all ligand is in its basic, carboxylate form, and the conventional and conditional stability constants are equal. For imidazole, 44% of the ligand is in the basic form. For glutathione and ammonia, only 1.2 and 0.47% respectively of the ligands are in the basic form.

Tab. 5 Conventional and conditional (pH 7.0) stability constants.

Ligand	pK_a	Ni^{2+}		Zn^{2+}		Cd^{2+}	
		log K_s	log K_7	log K_s	log K_7	log K_s	log K_7
Acetate (O^-)	4.7	0.7	0.7	0.9	0.9	1.3	1.3
Imidazole (=N)	7.11	3.0	2.6	2.52	2.2	2.80	2.4
Glutathione (RS^-)	8.92	4.0	2.1	5.0	3.1	6.16	4.2
Ammonia (NH_3)	9.33	2.79	0.5	2.31	0.0	2.65	0.3
Glycine	9.68	5.80	3.1	5.03	2.3	4.28	1.6
Histidine	9.15 6.10	8.7	6.5	6.6	4.4	5.4	3.2
1,2-Diaminoethane	10.0 7.2	7.3	3.9	5.7	2.3	5.4	2.0

Glutathione is the tripeptide γ-L-glutamyl-L-cysteinylglycine, and it serves as a superb model for unhindered sulfhydryl groups in proteins.

The results in Table 5 show that for all three metal ions, the ligand stabilities from the conventional constants follow the increasing sequence acetate < ammonia < imidazole < glutathione. This sequence differs from the stability order in neutral solutions because the sequence applies only when all ligands are predominantly in their basic form, which is true only for acetate. For conditional constants at pH 7.0, Table 5 shows that for Ni^{2+} the increasing stability order is ammonia < acetate < glutathione < imidazole, while for Zn^{2+} and Cd^{2+} the order is ammonia < acetate < imidazole < glutathione. For all three metal ions in neutral solutions, the most basic ammonia has become a weaker ligand than the least basic acetate. The stability order from conditional constants suggests that in neutral solutions, it is apt for Ni^{2+} to be found at imidazole sites and Zn^{2+} and Cd^{2+} at sulfhydryl groups. Of course, chelation by adjacent donors may increase stabilities and alter preferred binding sites. Yet, the examples in Table 5 serve as models for the analogous groups in proteins and prove that binding strengths and stability orders are pH-dependent.

In the nucleosides of the 6-oxopurines, guanosine and inosine, in neutral solutions, the much more basic N1 site is protonated while the N7 site is difficult to protonate. Metal ions coordinate in acid solutions at N7, and as the pH increases, they compete better with the proton and crossover to N1.

The principles developed in this section extend to ligands with several basic sites. For diamines, EDTA, and catecholates in which metal ions displace two protons in neutral solutions, the fraction of unbound, doubly deprotonated ligand becomes $\alpha = K_{a1}K_{a2}/[(H^+)^2 + (H^+)K_{a1} + K_{a1}K_{a2}]$, where $pK_{a1} < pK_{a2}$. Table 5 also concludes with two bidentate amine ligands and histidine. For 1,2-diaminoethane, the conditional stability constants at pH 7.0 are 3.4 log units less than tabulated stability constants.

Ignored in this section and Table 5 is the formation of metal ion hydroxo complexes and precipitates. Formulation of conditional stability constants that incorporate hydroxo complex formation is outside the scope of this section.

12
Cooperativity

Life abounds in cooperative interactions and would not exist, as we know it, without them. For example, the important enzyme that maintains the 20 000-fold Ca^{2+} gradient across cell membranes binds 2 Ca^{2+} or 2 protons so cooperatively that it is not possible to resolve reliably the successive stability constants. What is not appreciated, and what makes meaningless all calculations of the origin of life based on random events, is the cooperation that occurs in even the simplest systems. For statistical reasons at least, and in the case of charged ligands for electrostatic reasons as well, we expect the successive stability constants for ligand binding to a metal ion to decrease as the number of ligands increases. This decrease is generally observed. Yet, there are simple systems in which the second ligand is bound more strongly than the first.

Both the ammonia and imidazole complexes of Ag^{+} exhibit an inversion of the usual stability order: for NH_3, $\log K_1 = 3.20$ and $\log K_2 = 3.83$, while for imidazole, $\log K_1 = 3.1$ and $\log K_2 = 3.8$. Since there is a statistical factor of 4 or 0.60 log units favoring K_1 over K_2, the observed inversion is actually 1.23 to 1.3 log units or a factor of about 20. This result means that once the first ammonia molecule is bound, the second is bound significantly more strongly. Binding of two ligands to Hg^{2+} and four to Zn^{2+} also exhibits cooperative behavior. In these cases, the explanation lies in a decrease in coordination number upon ligand binding, resulting in shorter and stronger bonds to the remaining ligands.

In hemoglobin, the successive stability constants for dioxygen binding to the four iron-containing heme groups are cooperative with $K_1 < K_2 < K_3 \ll K_4$. In this case, the inverse order is caused by interactions among the α and β protein chains and is of enormous physiological significance. The inverse order means that once the first dioxygen binds, the second, third, and especially the fourth are bound even more avidly. As a result, wholly deoxygenated and wholly oxygenated forms predominate. They do so to such an extent that there are only small amounts of species with one, two, and three dioxygen molecules, and the individual stability constants are resolved with difficulty though the overall product $K_1K_2K_3K_4$ is well known. In an oxygen-rich environment such as the lung, hemoglobin becomes wholly oxygenated, while in an oxygen-poor tissue, the entire oxygen load undergoes efficient release.

13
Metal Ion Binding Characteristics

13.1
Amino Acids

Amino acids bind transition metal ions more avidly with increasing pH since the amino group suffers less competition from the proton. The potentially tridentate amino acids histidine and cysteine are especially strong transition metal ion binders. Alkali and alkaline earth metal ions, Al^{3+}, and lanthanides bind only weakly to amino acids.

13.2
Peptides

Owing to loss of basic carboxylate and amino groups, peptides usually bind metal ions more weakly than amino acids unless the metal ion deprotonates the peptide

nitrogen. The oxygen of a peptide bond is only a weak metal ion binder, and the peptide nitrogen is not a proton or metal ion binding site unless deprotonated. For amide deprotonations, $pK_a \approx 15$. A deprotonated peptide nitrogen serves as a strong metal ion binder, but unless there is an anchor for the metal ion, amide deprotonation does not take place until the solution is very basic. The Cu^{2+}–biuret reaction is an amide deprotonation in very basic solutions.

The tripeptide Gly-Gly-His serves as a strong quadridentate ligand with an amino nitrogen (an anchor), two deprotonated peptide nitrogens, and an imidazole nitrogen (a second anchor) providing a planar array of four donor atoms. Binding in this mode occurs best in neutral and even acidic solutions with Cu^{2+}, Pd^{2+}, and Ni^{2+}, which undergoes a transition from a blue, octahedral, high-spin complex to a yellow, planar, low-spin complex upon cooperative deprotonations of the peptide nitrogens. In blood, Cu^{2+} interacts in this binding mode with the amino terminus of human serum albumin where histidine is the third amino acid residue.

For neutral amides, the weakly basic oxygen ($pK_a \approx -1$) is the proton and metal ion binding site. The major determinant of peptide oxygen basicity is the basicity of the amino group making up the bond. Among the 20 amino acids in proteins, the amino group basicity of proline is almost 1 log unit greater than that of the other amino acids. As a result, the peptide oxygen from the amino acid linked to a proline nitrogen should be relatively basic compared to other peptide oxygens not linked likewise. Proline-linked peptide oxygens appear disproportionately as calcium ion binding sites in calcium proteins. Proline itself never furnishes the peptide oxygen that coordinates a metal ion. How much a relatively greater basicity, rather than appearance of proline in loop regions, contributes to proline-linked peptide oxygen occurrence as a metal binder remains uncertain.

13.3 Proteins

Metal ions interact in numerous ways with proteins, from the weak fairly nonspecific interactions of many metal ions with proteins such as serum albumin to the highly specific protein sites made for exclusive binding of a single kind of metal ion. For example, the iron-transporting protein of the plasma, transferrin, binds two Fe^{3+} under blood plasma conditions with conditional dissociation constants of 10^{-22} M. Such a minuscule value is necessary because the solubility of goethite, FeO(OH), only allows 10^{-21} M Fe^{3+} at pH 7.4. About 30% of all enzymes contain metal ions, and in most of these, only one kind of metal ion is bound almost exclusively. Individual cases are the subject of other articles in this volume.

13.4 Nucleosides

Let us designate the nucleic bases with their usual alphabetical symbols, A, C, G, T, and U. The order of decreasing basicity is given by

$$H^+: T3 > U3 > G1 \gg C3 > A1 > G7 > A7$$

In contrast, for a heavy-metal ion in neutral solutions, the order of decreasing stability is given by

$$\text{Heavy-metal ion: } G7 > A7 > C3 > A1 > G1 > U3 > T3$$

Comparison of the two series reveals a marked promotion of the G7 and A7 sites on passing from the first to the second series. Moreover, in the DNA double helix, the N7 sites are not involved in interstrand hydrogen bonding and are consequently relatively exposed. Thus, the antitumor *cis*-diaminodichloroplatinum(II) binds mainly at the guanosine N7 site of DNA. The sugar moiety binds metal ions very weakly and insignificantly.

Though proposed many times as metal ion binding sites, primary amino ($-NH_2$) groups located at C4 in cytidine, C6 in adenosine, and C2 in guanosine are neither proton nor metal ion binding sites in neutral solutions. These amino groups are not basic, the flat $-NH_2$ group is nearly coplanar with the ring, and the amino nitrogen–to-carbon bond lengths are about 6-pm shorter in the nucleic bases than in aniline. This combination of properties indicates appreciable double-bond character and extensive delocalization of electron density into the rings. Consistent with their appreciable *positive* charge density, the primary amino groups serve as hydrogen bond donors in specific base pairing. Moreover, in strongly acidifying solvents, even the dication of cytosine and the trications of adenine and guanine have still not undergone amino group protonation as the ring nitrogens and O2 in cytosine and O6 in guanine protonate before the amino group. Only upon its deprotonation in strongly basic solutions does the primary amino group ($pK_a \approx 16$) coordinate a few strongly binding metal ions such as CH_3Hg^+.

13.5
Nucleic Acids

With the introduction of more than one basic phosphate group, the di- and tri-nucleotides ($pK_a = 6.5$) become strong metal ion binders. Virtually all reactions of ATP require a Mg^{2+} cofactor, and ATP occurs as a Mg^{2+} complex in cells. Nucleic acid chemists were slow to recognize the role of ambient metal ions in stabilizing polymeric nucleic acid structures. With a negative charge on the phosphate of each residue, only a random-coil form exists at low salt concentrations. The phosphate groups in the polymers are not basic ($pK_a \approx 1$) and bind metal ions very weakly. Required for structures such as the double helix are nonspecifically bound alkali metal ions and Mg^{2+} serving as counterions to offset the negative charges on the phosphates. Mg^{2+} is also important in stabilizing various RNA structures.

14
Dioxygen

It is impossible to overstate the effects that increases in the dioxygen content of the atmosphere have wrought for life on Earth. On primitive Earth, the atmosphere was free of dioxygen, and beginning about 3 500 million years ago, anaerobic prokaryotes thrived. About 2 700 million years ago, prokaryotes began emitting dioxygen, and the atmospheric content began increasing. Soluble Fe^{2+} was oxidized to Fe^{3+}, which formed a very insoluble goethite, $Fe(OH)_3$, that allows only 10^{-20} M free Fe^{3+} at pH 7.0. (For a typical cell volume of 10^{-12} L, this implies only one Fe^{3+} ion in 10^8 cells!) Thus, this important and formerly freely available element became scarce, and it was necessary for nature to find new ways to handle it. The ever-increasing dioxygen concentration became an environmental catastrophe for an anaerobe unable to find a niche or evolve.

However, by allowing a greater diversity of energy-producing reactions, the increasing dioxygen concentration promoted the rise of eukaryotes about 1 500 million years ago and of the first multicellular organisms about 650 million years ago.

Prokaryotes do not form true multicellular structures. Later, sunlight interacting with dioxygen made enough ozone in the stratosphere to provide an umbrella for ultraviolet radiation, so that about 410 million years ago, plants were able to invade the land. Thus, though life appeared at just about the first 1 000 million years of the earth's history, it took over 3 000 million years from the origin of life on earth through the production of a dioxygen-containing atmosphere and ozone shield to extensive land plants. Dioxygen is the pivotal element the absence or presence of which determines the forms of life on earth. It took more than 2 000 million years after the first appearance of dioxygen in the atmosphere to yield an environment in which multicellular organisms arose and became the basis for life as we know it today.

Dioxygen, so necessary for the life forms on earth today, is also toxic and contributes to cell aging. With two unpaired spins, O_2 reacts readily with radicals and some metal ion complexes. Subsequent reactions generate other reactive molecules and radicals: hydrogen peroxide, H_2O_2; hydroperoxides, ROOH; superoxide, O_2^-; and the hydroxyl radical, HO, which is highly damaging. The last two species initiate deleterious radical chain lipid peroxidations that contribute to aging. Therefore, pivotal dioxygen provides life with both the source of its versatility via oxidation processes and the seeds of its demise by radical reactions.

Almost all organisms possess an enzyme, superoxide dismutase, to rid cells of readily generated and reactive superoxide, O_2^-, by converting it to less-toxic hydrogen peroxide, $2\ O_2^- + 2H^+ \rightarrow H_2O_2 + O_2$. Superoxide dismutase is much more widespread than catalase, which catalyzes the decomposition of hydrogen peroxide.

15
Metal Ion Complexation Kinetics

Belying a common understanding of the word *formation* that might imply an addition reaction, metal ion complex formation in solution is almost always a *substitution* (occasionally with a reduction in coordination number). In aqueous systems, bound water undergoes substitution either in the reactant complex or as an intermediate in the route from reactants to products.

15.1
Substitution Reactions

The greater complexity of kinetics over thermodynamics is shown in the simple-appearing ligand replacement reaction with n fixed ligand donor atoms, L, bound to metal ion M (charges not specified).

$$L_nMX + Y \longrightarrow L_nMY + X$$

While thermodynamics deals with the species above, kinetics also includes additional species involved in the mechanism of the reaction. Substitution of unidentate ligand X by unidentate ligand Y may proceed by a reduction of coordination number (dissociation) to give the intermediate L_nM, by an increase in coordination number (association) to yield the intermediate $L_nM(X)Y$, or by a process in which the incoming and outgoing ligands interchange in a more or less concerted fashion. From the wholly dissociative mechanism

through the varying degrees of the interchange route to the wholly associative mechanism, there is a continuous spectrum of possibilities. Moreover, in aqueous systems, virtually all such substitution reactions occur via an aquo intermediate $L_nM(OH_2)$. Thus, for the most general case in which X and Y are not water, the question just posed as to the coordination number of the intermediates needs to be answered twice: for both formation and reaction of the aquo intermediate.

Detailed answers about the mechanism of substitution reactions in metal ion complexes have been sought for many years. Some general conclusions now seem reliable, but universal agreement on all details remains to be reached. *Two statements sum up many of the results*: (1) since room is available for approach of an axial ligand, most substitutions in linear, trigonal, and planar complexes proceed by the associative mechanism with an increase in coordination number and (2) since the environment about the metal ion is more crowded, most substitutions in octahedral complexes proceed in the interchange-dissociative region of the continuum.

15.2 Ligand Exchange

Even if they do not appear as reactants or products, the intermediacy of aquo complexes in most substitution reactions, whatever the detailed mechanism of substitution in any particular case, makes the properties of the aquo complexes of primary importance.

The characteristic rate constant for exchange of inner-sphere water (both X and Y are H_2O in the above reaction) gives insight into the differences among metal ions. Increasing water exchange rates on wholly aquo metal ions follow the order

$$Cr^{3+}, Ru^{3+} \ll Pt^{2+} \ll Ru^{2+} < Co^{3+} < Al^{3+} \ll V^{2+}, Fe^{3+} < VO^{2+}, Ga^{3+}, V^{3+}, Pd^{2+}, Be^{2+} < Ni^{2+} < Mg^{2+} < Co^{2+}, Fe^{2+} < Mn^{2+}, Zn^{2+}, Sc^{3+} < Ca^{2+}, Cd^{2+}, Gd^{3+} < \text{alkali metal ions}, Cr^{2+}, Cu^{2+}, Hg^{2+}, Pb^{2+}$$

with each inequality sign indicating an approximate 10-fold increase in rate. Water exchanges slowly with the first 6 aqua cations through Al^{3+}, rapidly with the next 14 through Sc^{3+}, and virtually instantaneously with the last 8 entries. The series spans a phenomenal 15 powers of 10 from a lifetime at 25 °C of about 5 days for the mean time of a water molecule on aqueous Cr^{3+} to 10^{-9} s for the metal ions at the end of the list. Indeed, exchange lifetimes are so short for the cations in the last line that some values are not known with certainty: some of the lifetimes may be 10^{-10} s or even shorter.

The above series is useful in several ways. The contrast between the presence of Zn^{2+} in numerous mammalian enzymes and of Ni^{2+} in only a few plant enzymes has proved puzzling. Ni^{2+} differs by neither size nor most complex stabilities from Zn^{2+}. The above exchange rate series explains the difference since Zn^{2+} undergoes ligand exchange about 10^3 times faster than Ni^{2+}, a significant factor for a metal ion bound at enzyme active sites.

In four cases, reduction of the metal ion substantially increases the rate. An approximate 10^4-fold rate increase occurs for the $d^5 \rightarrow d^6$ reduction in both Ru^{3+} and Fe^{3+}. An even greater 10^7-fold rate increase takes place upon the reduction of $Co^{3+} \rightarrow Co^{2+}$. Finally, the 10^{15} span of the entire series is gained upon reduction of $Cr^{3+} \rightarrow Cr^{2+}$.

Though these lifetimes refer to water exchange in the wholly aquated metal ions, they also reflect the relative rates of exchange of other ligands. When bound to a metal ion, other ligands, including hydroxide ion, increase modestly the release rate of bound water, typically by about 10^2. As a poorer leaving group, hydroxide ion itself exchanges much more slowly than water. Chelated ligands exchange more slowly, but again, the relative order prevails. In the case of chelates, binding occurs first by one donor group followed by chelate ring closure. In some cases, such as five-membered rings, the chelate ring closes rapidly, and in others, especially with larger rings, ring closure may become the slow step. Selective broadening of lines in nuclear magnetic resonance spectroscopy that have been used to indicate the binding site of a paramagnetic metal ion at stoichiometric concentrations often fails. This occurs because chelate ring closure is slow compared to rapid passage of the metal ion to other ligands present in large excess, which bind only in a unidentate mode.

We conclude with an application that incorporates many of the principles mentioned in this chapter. Surprisingly, the above exchange rate series demonstrates that some of the strongest-binding metal ions undergo the most rapid ligand exchange. Examples from the high-rate end of the series include Pb^{2+}, Hg^{2+}, Cu^{2+}, and Cd^{2+}, all strong ligand binders. A significant feature of the toxicology of Hg^{2+} and CH_3Hg^+ is the rapid exchange of ligands in and out of coordination to the metal ion. For CH_3Hg^+ binding to the sulfhydryl group of glutathione (present in blood plasma at 4 mM), the stability-constant logarithm is an extraordinary $\log K = 15.9$. For such strong binding, the half-life for exchange by a dissociative mechanism is about 10 days. Yet, the average lifetime for the CH_3HgSR complex in the presence of excess glutathione is less than 0.01 s. This comparison shows that exchange does not occur by a dissociative mechanism. The ability of linear two-coordinated Hg^{2+} and CH_3Hg^+ to associate weakly with additional donor atoms accounts for rapid metal ion exchange among donor atoms. The last two ligands are bound much more weakly than the first two and exhibit longer Hg-to–donor atom bond lengths. Excess ligand participates in nucleophilic attack at an uncoordinated site on the metal ion with rearrangement in the coordination geometry and release of a formerly bound ligand. This addition–elimination mechanism accounts for the very rapid exchange in Hg^{2+} and CH_3Hg^+ complexes.

Second Messenger
An intracellular molecule, generated by the cell in response to an extracellular signal (first messenger), which triggers a biochemical cascade leading to a change in the function or phenotype of the cell.

The biological activity of many proteins is modulated by the phosphorylation of specific sites within the protein. Protein kinases catalyze the transfer of a phosphate group to the protein, while protein phosphatases remove the phosphate group. This reversible modification is utilized by the cell to dynamically regulate proteins that are involved in almost all cellular functions. Protein phosphorylation plays a particularly prominent role in the transduction of extracellular signals. A hormone, neurotransmitter, or growth factor binds to its cell surface receptor and may directly or indirectly activate a protein kinase (or phosphatase) inside the cell, which leads to changes in the phosphorylation states of key regulatory proteins. This cascade of events ultimately results in a functional or phenotypic cellular response (e.g. contraction, release of neurotransmitter, changes in metabolism, or altered gene expression).

1 Importance of Protein Phosphorylation in Biological Regulation

Protein phosphorylation is one of the most common posttranslational modifications to occur in eukaryotic cells. It has been estimated that ~30% of proteins encoded by the human genome are phosphorylated at one or more sites. Phosphorylation and dephosphorylation is a fundamental molecular switch used by cells to control the activity of a variety of cellular proteins, which in turn regulates a vast array of cellular functions. The types of proteins known to undergo reversible phosphorylation include metabolic enzymes, cytoskeletal proteins, transcription factors, ion channels, and cell surface receptors. Protein phosphorylation is particularly prominent in signal-transduction processes. A cell can rapidly respond to a biological signal by phosphorylating key intracellular molecules thereby initiating a cascade of events resulting in a change in a physiological property such as cell motility, release of neurotransmitters, modulation of ion fluxes or alteration in gene expression. Because of the prominent role of this reversible and tightly coupled protein-modifying process, dysregulated protein phosphorylation can contribute to the pathogenesis of human disease.

The phosphorylation state of a particular protein is controlled by specific protein kinases and phosphoprotein phosphatases (Fig. 1). Protein kinases are enzymes that transfer the γ-phosphate from a nucleoside triphosphate (usually ATP) to an amino acid side chain of the substrate protein. Structural studies have shown that, in the case of enzymes, phosphorylation can occur within the active site and directly affect substrate binding. Phosphorylation

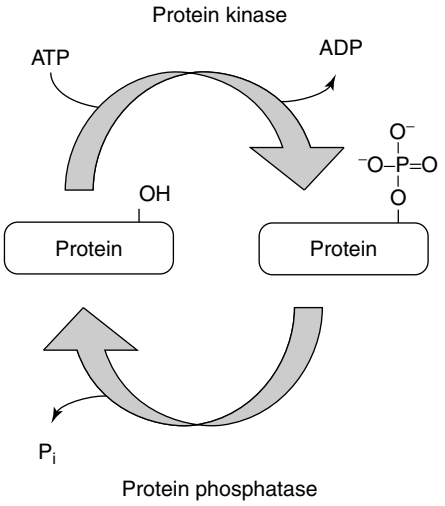

Fig. 1 Protein kinases catalyze the transfer of a phosphate group onto a specific amino acid side chain of a substrate protein. ATP usually serves as the phosphate donor, and serine, threonine, and tyrosine residues serve as phosphate acceptors. The reversible phosphorylation of a protein causes a change in its biological activity. Phosphoprotein phosphatases remove the phosphate group allowing the protein to return to its former functional state. The relative activities of the protein kinase and protein phosphatase generally determine the phosphorylation state of the protein. (Modified from Scott and Patel, Encyclopedia of Human Biology (1991) 6; 201–211; reproduced by permission of Academic Press.)

can also occur at sites distal to the catalytic site and regulate enzyme function by inducing long-range conformational changes. Phosphorylation has been shown to affect the biological properties of proteins by altering their intracellular location, enhancing their susceptibility to proteolysis, and modulating their ability to interact with other proteins. Phosphoprotein phosphatases remove the phosphate group, thereby allowing the protein to return to its previous functional state. Some proteins become active when dephosphorylated and are inactivated by phosphorylation. An example is glycogen synthase, an enzyme that catalyzes the conversion of glucose to glycogen. This enzyme is active in the dephosphorylated form. When phosphorylated by glycogen synthase kinase 3 (GSK3), glycogen synthase becomes inactive thereby limiting the synthesis of glycogen. In general, both protein kinases and phosphoprotein phosphatases are under stringent regulatory control. The activation state of the relevant kinase and phosphatase will usually determine when a protein becomes phosphorylated and how long it remains phosphorylated.

2 Classification and Properties of Protein Kinases

Protein kinases share a highly conserved catalytic domain called the *kinase domain* (also known as the *catalytic core*). The high conservation of this domain has helped identify protein kinase genes from the various large-scale genome sequencing efforts of human, yeast (*Saccharomyces cerevisiae*), fly (*Drosophila melanogaster*), and worm (*Caenorhabditis elegans*). Over 500 protein kinase genes have been identified in the human genome, representing about 2% of the human genes. The kinase domain is the third most abundant domain encoded in the human genome, with the immunoglobulin and zinc finger domains being the most prevalent.

More than 170 crystal structures of protein kinases have been resolved, providing an insight into the structure and function of these enzymes. The kinase domain contains two major structural domains named N- and C-terminal domains (Fig. 2). These two domains are bridged through a short linker peptide, around which they rotate in

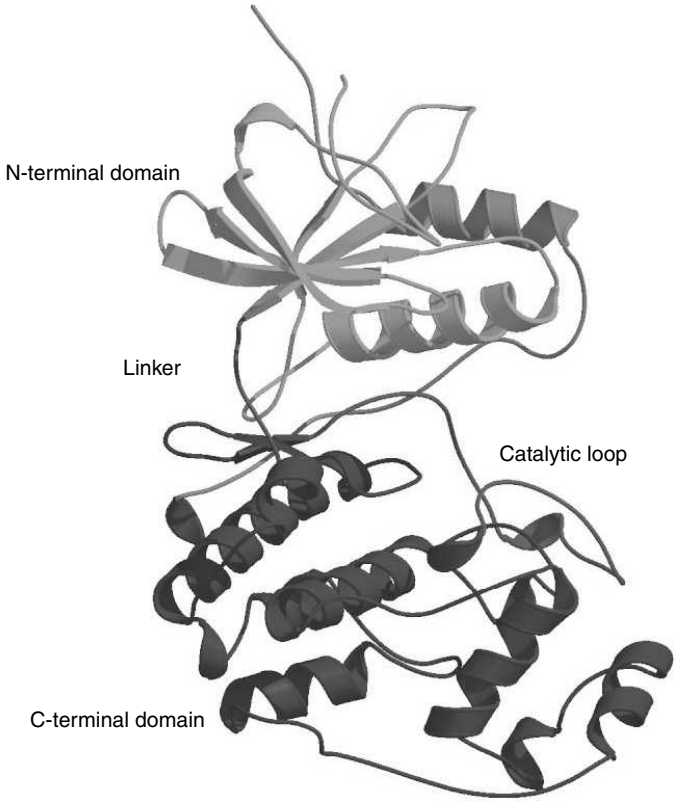

Fig. 2 Ribbon diagram of the kinase domain of ERK2 (p42 MAPK), a protein serine–threonine kinase. The four prototypic subdomains are labeled and color-coded.

response to protein substrate and/or ATP-binding. Also located in the C-terminal domain is a short peptide strand called the *catalytic loop*, which contains an invariant aspartate that is critical for catalysis. The ATP binds in a deep cleft between the N- and C-terminal domains that contain a part of the linker region and the catalytic loop. The protein substrate binding site is composed of shallow surface depressions, whose structural features vary among different protein kinases and thereby influence substrate specificity. The shallow surface depressions do not provide adequate interaction sites for high affinity binding of small molecules. Thus, the vast majority of small-molecule inhibitors identified so far bind to the ATP binding site.

Protein kinases recognize phosphorylation sites within particular amino acid sequences called *consensus sequences* or *recognition motifs*. Studies using peptide substrates containing altered amino acid sequences have revealed the importance of primary sequence in distinguishing phosphorylation sites. For example, cAMP-dependent protein kinase will phosphorylate a serine or threonine residue in the sequence -Arg-Arg-*X*-Ser/Thr-*X*-, where *X* represents any amino acid. Eliminating

or displacing either arginine residue can dramatically alter the kinetics of phosphorylation. Although amino acid sequence is an essential determinant for substrate recognition, higher orders of structure can also affect phosphorylation. Conformational states that mask or expose phosphorylation sites can alter the phosphorylation of the substrate protein. Many protein kinases can provide additional substrate specificity by engaging substrate with domains outside the catalytic core, such as SH2 (src homology 2) domains.

Protein kinases are classified according to the amino acid residue they phosphorylate. Greater than 98% of phosphorylation events in eukaryotic cells occur on serine and threonine residues (by protein–serine/threonine kinases); the remainder occur on tyrosine residues (by protein tyrosine kinases). A few protein kinases appear to phosphorylate tyrosine as well as serine/threonine residues and are classified as dual specificity protein kinases. Tyrosine kinases (TK) are found only in metazoans, whereas serine/threonine kinases are conserved throughout the eukaryotes. The lipid kinase PI3K possesses protein–serine/threonine kinase activities, in addition to phosphorylating lipid phosphoinositides. Histidine–aspartate kinases have been identified in bacteria, yeast, and plants but are not known to exist in mammals.

By aligning the kinase domain amino acid sequences for all the protein kinases, one can develop a sequence-based hierarchy of groups, families, and subfamilies (Fig. 3). Serine/threonine kinases are divided into 5 groups and further divided into 89 families. Tyrosine kinases, which represent a small fraction (~15% in humans) of the kinase superfamily, constitute a single group (TK) of 30 families. This phylogenetic classification of protein kinases correlates closely with general themes of protein kinase function and regulation. For example, the TK group is composed of tyrosine kinases only, which are widely recognized for their roles in controlling cell growth and differentiation. The group of Ca^{2+}/calmodulin-dependent protein kinases (CAMK) tend to phosphorylate serine/threonine residues located near basic residues. Many protein kinases in this group are activated by Ca^{2+}/calmodulin binding to a small domain located C-terminal to the catalytic domain.

Tyrosine kinases were identified first as the products of viral oncogenes. These viral protein tyrosine kinases, which we now know are structural variants of normal cytoplasmic protein tyrosine kinases, have unregulated tyrosine kinase activity and thereby induce the malignant transformation of cells. Their normal cellular homologs are under stringent regulatory control and play critical roles in cell growth and metabolism. Another important example of cytosolic nonreceptor tyrosine kinases is the Janus (JAK) kinase family. The JAKs are involved in signal transduction of the cytokine receptor superfamily. JAKs bind to cytoplasmic domains on cytokine receptors and become activated when the receptor binds its ligand. The activated JAK phosphorylates the receptor and intracellular proteins such as STATs. Once phosphorylated, STATs translocate to the nucleus where they regulate gene expression.

Some tyrosine kinases are cell surface receptors that contain an intrinsic tyrosine–protein kinase within their cytoplasmic domains. These receptor tyrosine kinases constitute a significant portion of the TK group. Of the 90 protein tyrosine kinases found in humans, 58 are

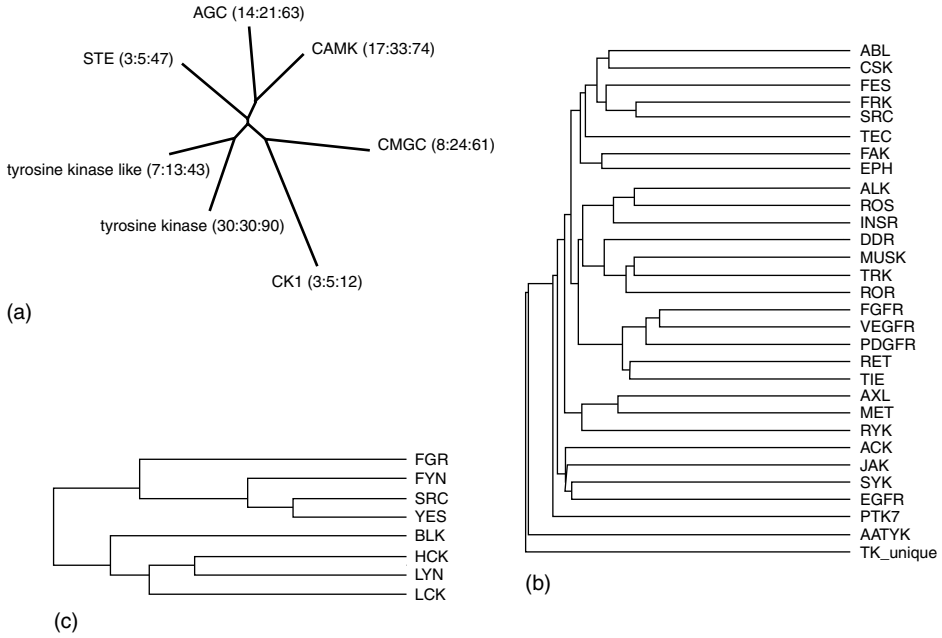

Fig. 3 Dendrogram or phylogenetic tree of protein kinases. (a) A circular tree representing the evolutionary divergence of the eukaryotic protein kinase groups based on the homology within the kinase domains. Each group can be further divided into families and in some instances into subfamilies. For example, the AGC group includes the cyclic nucleotide-regulated protein kinase family, which can be divided into the cAMP-dependent and cGMP-dependent protein kinase subfamilies. The numbers in parentheses in (a) represent the number of families, subfamilies, and human kinases in each protein kinase group. (b) The tyrosine kinase group can be divided into 30 families, as depicted in the flat tree. (c) The src family of tyrosine kinases contains 8 human tyrosine kinases and their evolutionary divergence is depicted. A comprehensive classification scheme for each protein kinase group is available at www.kinase.com.

the receptor type. Examples of receptor tyrosine kinases include the EGF receptor and the PDGF receptor. These receptors undergo dimerization following ligand binding. Receptor dimerization leads to activation of the receptor tyrosine kinase and autophosphorylation of the receptor on multiple tyrosine residues. The phosphorylated tyrosine and surrounding amino acids serve as binding sites for secondary signal transducing proteins containing SH2 domains, for example, Src, phospholipase C-γ, phosphatidylinositol 3′ kinase, and *ras* GTPase-activating protein (GAP). Specificity of binding is generated by the sequence context surrounding the individual phosphotyrosines. These newly bound proteins link the receptor with a variety of different signal-transduction pathways either directly due to the activation of their catalytic activity or indirectly by serving as an adaptor protein to couple other signal-transduction molecules.

Eph receptors, the largest family of receptor tyrosine kinases, are unique in that their ligands, ephrinAs and ephrinBs, are cell surface proteins. The interaction of ephrins with Eph receptors on opposing

cells induces receptor clustering and phosphorylation, and subsequent recruitment of intracellular signaling molecules. The binding of ephrin to the Eph receptor also initiates a functional response in the ligand-expressing cell, although the biochemical mechanism for this effect is not yet clear. Such reciprocal signal-transduction between Eph receptors and their ligands regulate cell–cell repulsion and adhesion mechanisms involved in the formation and maintenance of organ systems.

Several serine/threonine-receptor kinases exist. These include lectin receptor kinases, transforming growth factor β (TGF-β) receptors, and activin. TGF-β receptors (types I and II) control the development and homeostasis of most tissues in metazoan organisms. To exert their signal, type II and type I receptors act in sequence. TGF-β first binds to the type II receptor, which contains intrinsic kinase activity. The type I receptor is then recruited and phosphorylated in its intracellular domain by the type II receptor, leading to activation of its kinase activity. Similar to JAK-STAT signaling, activated type I TGF-β receptor recruits and phosphorylates Smad proteins, which then translocate into the nucleus where they regulate gene transcription.

Mechanistically, many protein kinases are regulated through autoinhibition. This involves a pseudosubstrate domain, found either in the primary sequence of the kinase itself or on a separate regulatory protein that interacts with the active site. Activation is achieved when the autoinhibitory domain is displaced from the active site. Protein serine/threonine kinases activated by second messengers, intracellular molecules that are generated in response to extracellular signals (Fig. 4), are kinases regulated by autoinhibition. For these enzymes, binding of the second messenger induces a conformational change that releases the inhibitory domain. These protein kinases are classified according to the second messenger that stimulates their activity. These groups include protein kinases activated by cyclic nucleotides (cAMP- and cGMP-dependent protein kinases), calcium plus calmodulin (including Ca^{2+}/calmodulin-dependent protein kinase II and myosin light-chain kinase), and diacylglycerol (protein kinase C). In the protein tyrosine kinase Src, activation arises from phosphorylation-induced conformational changes, resulting in displacing part of the C-terminal tail that otherwise occupies the active site and prevents substrate from binding to enzyme.

Activation of many protein kinases, but not all, require phosphorylation of either a conserved threonine or tyrosine residue in a loop structure called the activation loop (Fig. 2). These protein kinases have low basal activities as a result of the unphosphorylated form possessing low affinity for ATP and incorrectly positioned catalytic residues. Phosphorylation induces a structural change in the activation loop, which results in remodeling of the active site leading to optimized substrate binding and catalysis.

3 Classification and Properties of Phosphoprotein Phosphatases

Traditionally, phosphoprotein phosphatases were categorized by their selectivity for phosphoserine/phosphothreonine or phosphotyrosine residues and further separated on the basis of sensitivities to endogenous inhibitors, requirements for cations, and *in vitro* substrate specificity. More recent gene sequencing efforts

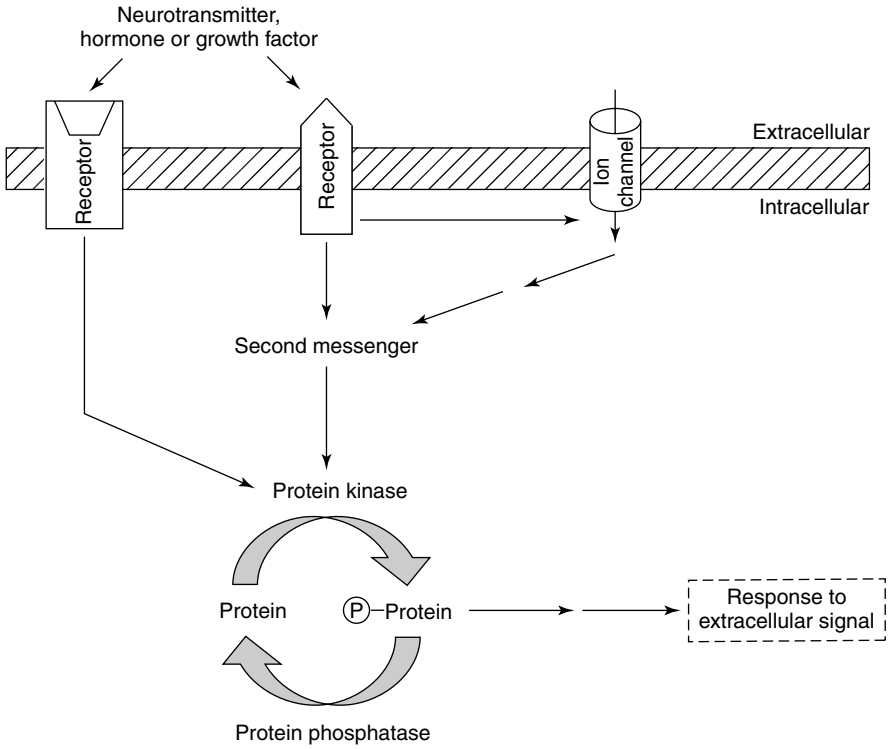

Fig. 4 Protein phosphorylation is a common mechanism used to transduce extracellular stimuli into intracellular responses. Extracellular molecules bind to their cell surface receptors and activate protein kinases or phosphatases. Some kinases and phosphatases are intrinsic components of receptors and are directly activated by ligand binding. Others are activated, either directly or indirectly, by changes in the levels of second messengers such as cAMP, cGMP, diacylglycerol, and Ca^{2+}. The activity of some kinases and phosphatases are regulated by other kinases and phosphatases as part of a phosphorylation cascade. (Modified from Scott and Patel, Encyclopedia of Human Biology (1991) 6; 201–211; reproduced by permission of Academic Press.)

have revealed three distinct superfamilies of phosphatases; two families of protein serine/threonine phosphatases (PPP and PPM families) and one protein tyrosine phosphatase family (PTP). Within the PTP family is a subgroup of enzymes that dephosphorylate both tyrosine and serine/threonine residues: this group is called the *dual-specificity phosphatases*.

Thirty-two protein-serine/threonine phosphatase genes have been identified in the human genome sequence. The enzymes encoded by these genes are responsible for dephosphorylating proteins that are acted upon by over 500 serine/threonine kinases. Thus, it is very likely that most serine/threonine phosphatases will have multiple substrates. In most cases, the catalytic subunits of these phosphatases are capable of binding to numerous regulatory and targeting subunits. These auxiliary subunits are expressed in cell-type specific patterns and can be located within different regions of the cell. They regulate

the biological activity and subcellular location of the phosphatase and thereby limit access to potential substrates. Thus, one serine/threonine phosphatase can be utilized within the cell to regulate multiple cellular events.

The PPP family of serine/threonine phosphatases has the most members and is responsible for more than 90% of the serine/threonine phosphatase activity in mammalian cells. This family includes some of the earliest and most extensively studied enzymes including PP1, PP2A, and PP2B (also called calcineurin). The principal members of the PPM family include PP2C and pyruvate dehydrogenase phosphatase. Although these enzymes are unrelated to the PPP family in terms of protein sequence, they share structural features within their active sites and have a common catalytic mechanism.

Compared with the serine/threonine phosphatases, the tyrosine phosphatases have different structural features within their catalytic domains and use a different molecular mechanism for catalysis. The tyrosine phosphatases share a common amino acid sequence within their active site termed the *PTP signature motif*. Although the PTPs are responsible for a very small fraction of the overall cellular phosphatase activity, data from the human genome project predict over one hundred human enzymes. These phosphatases can be divided into three subfamilies: tyrosine-specific, dual-specific, and low-molecular weight phosphatases.

Some of the tyrosine-specific phosphatases have transmembrane receptor-like structures with an intracellular catalytic domain, suggesting the existence of receptor-linked proteins that utilize the dephosphorylation of tyrosine residues for signal transduction. Other tyrosine-specific phosphatases are intracellular enzymes that contain SH2 domains allowing them to interact with either receptor or cytosolic protein tyrosine kinases or localize to different subcellular regions where they function. The dual-specificity phosphatases include the Cdc25 and mitogen-activated protein kinase (MAPK) phosphatase families. The Cdc25 phosphatases are highly specific for adjacent phosphothreonine and phosphotyrosine residues on cyclin-dependent kinases. The regulated dephosphorylation of these sites plays a crucial role in eukaryotic cell cycle progression. The MAPK phosphatases regulate signal transduction pathways that are activated by mitogens and stress and which control cell proliferation, differentiation, and death (apoptosis). Much has been learned about the structure of PTPases, but many questions on their function and physiological substrates remain. This is especially true for the low molecular weight tyrosine phosphatases, a family of enzymes whose biological function(s) remain undefined.

4 Phosphorylation Cascades and Multisite Phosphorylations

Protein kinase cascades represent a common underlying theme in many signal-transduction pathways. A classical example is the regulation of glycogenolysis in skeletal muscle. Epinephrine binds to the β-adrenergic receptor, causing activation of adenylate cyclase, an increase in cAMP production, and an activation of cAMP-dependent protein kinase. This enzyme phosphorylates and activates phosphorylase kinase, which in turn phosphorylates and activates glycogen phosphorylase. In addition, cAMP-dependent protein kinase

phosphorylates and inactivates phosphoprotein phosphatase-1. Because a single protein kinase molecule can phosphorylate many substrate molecules, each step in this cascade amplifies the signaling pathway. In addition, some protein kinases in these cascades can phosphorylate many different substrate proteins, thereby modulating multiple biochemical pathways, which lead to an amplification of a signal. This is most prominent in the MAPK cascade. In response to an extracellular stimulus, several stress-activated protein kinases also converge onto key protein kinases, resulting in the amplification of a cell stress signal. Thus, protein kinase cascades contain sequential steps to amplify an extracellular signal as well as divergent steps to coordinate different cellular processes.

Many proteins appear to be phosphorylated at multiple sites with varying consequences on their biological activity. Examples of multisite phosphorylation have revealed that (1) different protein kinases can phosphorylate a common site on a protein; (2) different protein kinases can phosphorylate distinct sites on a protein yet produce similar changes in biological activity; (3) different protein kinases can phosphorylate distinct sites on a protein resulting in opposite changes in biological activity; and (4) phosphorylation of one site by a protein kinase can generate a consensus sequence for a second protein kinase. Proteins that are phosphorylated at multiple sites often function at critical points in a biochemical cascade. Thus, multisite phosphorylation represents one approach by which different biological signals, acting through different transduction pathways, can converge to regulate the function of a single protein. This convergence would allow for coordinated regulation of a single cellular process. Reversible phosphorylation of proteins represents a unifying and dynamic mechanism by which different signaling systems can be integrated to produce the appropriate biological response.

5 Genetic and Pharmacological Modulation of Protein Phosphorylation

In 1979, the following four criteria for establishing that an enzyme undergoes physiologically significant phosphorylation were defined:

1. The enzyme is phosphorylated at stoichiometric levels at a significant rate by a protein kinase and is dephosphorylated by a protein phosphatase.
2. There is a correlation between the degree of phosphorylation of an enzyme and changes in its functional properties.
3. *In vivo* studies or studies with intact cells show that the enzyme can be phosphorylated and dephosphorylated with subsequent changes in its functional properties.
4. The cellular levels of protein kinase and phosphatase effectors correlate with the extent of phosphorylation of the enzyme.

These criteria can be extended to all other classes of phosphoproteins such as receptors, ion channels, and proteins that form the cytoskeleton and proteins that regulate transcription and translation. Of these four criteria, the third element is often difficult to demonstrate. Selective activators or inhibitors of a specific protein kinase or phosphatase are often used

in an attempt to modify the phosphorylation state of a particular protein in intact cells and to test for changes in its biological activity. By incubating cells with a molecule that selectively activates or inhibits a particular kinase or phosphatase, one can study the downstream events that develop as a consequence of the pharmacological manipulation. The number of pharmacological agents that target protein kinases and phosphatases have increased significantly in recent years, and have been used to provide a wealth of information linking a particular enzyme with a particular biological response. Agents that modify protein phosphorylation can be classified into a number of different categories including activators or inhibitors, and natural or synthetic molecules. The synthetic molecules can be further separated into small molecules, peptides/proteins, and nucleic acids (e.g. antisense oligonucleotides and small interfering RNAs to regulate expression of an enzyme). Regardless of the classification scheme, these agents have great value when trying to identify the physiological substrates for a particular kinase or phosphatase, and to dissect the role of a particular phosphoprotein in cell function.

Several synthetic analogs of cAMP have been developed and shown to activate cAMP-dependent protein kinase in a manner analogous to cAMP. Some of these compounds are membrane-permeable and therefore can activate the enzyme when applied to intact cells. Because these compounds effectively mimic the actions of extracellular signals on the cAMP signal-transduction pathway, these cAMP analogs are useful to determine if a cellular response to a particular hormone, growth factor or neurotransmitter is mediated through the cAMP pathway.

Phorbol esters are a class of small organic molecules first identified in croton oil. These compounds mimic the actions of diacylglycerol and activate members of the protein kinase C family. Both diacylglycerol and inositol trisphosphate are generated by the hydrolysis of inositol phospholipids, which occurs in response to a number of different extracellular signals. Diacylglycerol activates the protein kinase C signal-transduction pathway while inositol trisphosphate stimulates the release of calcium from intracellular stores. Because the phorbol esters are potent and selective activators of protein kinase C in intact cells, they have become invaluable tools for investigating the involvement of protein kinase C isoenzymes in various biochemical pathways and to dissociate responses mediated via the diacylglycerol signal-transduction pathway from the inositol trisphosphate pathway. However, caution must be used when interpreting the results from such experiments, for recent studies have revealed additional targets for diacylglycerol and phorbol esters that can regulate cell function independent of protein kinase C.

Several natural toxins have been identified that exert their biological effects through direct and potent inhibition of the phosphatases PP1 and PP2A. These toxins are found in biologically diverse organisms. Okadaic acid, the first inhibitor identified within this class, is produced by several species of marine plankton. This plankton can accumulate in shellfish and, when ingested by humans, cause an illness termed diarrhetic seafood poisoning. Cantharidin is another interesting example, for it has a rich history of medicinal and recreational use prior to understanding its mechanism of action. Cantharidin is produced by the blister beetle as a defense mechanism against predators. The

dried bodies of these beetles have been used in China for over 2000 years as a traditional medicine for several indications including cancer and piles. Hippocrates also described its use for the treatment of dropsy. It has been exploited (incorrectly) as an aphrodisiac named Spanish Fly because it is an irritant of the urogenital tract, and causes pelvic engorgement in women. More recently, dermatologists have used it as a topical agent for the treatment of warts. Because cantharidin has a relatively simple molecular structure, a long history of apparent medicinal value and a newly discovered molecular mechanism of action, drug hunters have begun to synthesize derivatives of cantharidin in search of new medicines with greater specificity for a subset of serine/threonine phosphatases, thereby reducing side effects that occur with nonselective inhibitors.

In recent years, the development of genetically modified organisms has provided important tools for research. These organisms have been particularly helpful in evaluating whether phosphorylation by a particular kinase affects a protein's function *in vivo*. New molecular and genetic techniques have been developed to create animals expressing kinases that are driven by cell-specific or developmentally regulated promoters. Knockout mice have been generated carrying targeted mutations that prevent the expression of a functional enzyme. Animals derived from such work have greatly enhanced our understanding of protein phosphorylation pathways involved in pathological conditions such as diabetes, Alzheimer's disease, and cancer.

Modulators of protein phosphorylation are useful not only to dissect and understand molecular mechanisms but, as noted above for cantharidin, may also have therapeutic value. For example, FK506 and Cyclosporin A are drugs that produce their pharmacological effects by inhibiting a serine/threonine phosphatase in T-lymphocytes and preventing the dephosphorylation of a key cellular protein. They are used therapeutically as immunosuppressive drugs and are prescribed to organ-transplant patients. FK506 and Cyclosporin A bind to their respective intracellular binding proteins, FKBP12 and cyclophilin A. Each of these complexes can bind to PP2B and block its activation. Normally, T-cell activation causes an increase in intracellular calcium, which stimulates PP2B. Active PP2B dephosphorylates the transcription factor NF-AT thereby facilitating its translocation to the nucleus to initiate gene transcription. FK506 and Cyclosporin A block the dephosphorylation of NF-AT, preventing transcription of specific genes in T-lymphocytes that induce transplant rejection.

Current drugs for cancer therapy include cytotoxic agents that target basic cellular processes such as DNA replication or microtubule dynamics. Drug discovery strategies aimed at inhibiting specific protein kinases have led to the discovery of compounds that, in theory, should be effective and more tolerable anticancer therapies. Several dozen compounds are now in clinical trials for a wide range of cancers. Two protein kinase inhibitors have demonstrated remarkable clinical value and have been approved by the FDA: Gleevec, a Bcr-Abl kinase inhibitor for the treatment of chronic myelogenous leukemia, and Iressa, an epidermal growth factor receptor kinase inhibitor for the treatment of advanced non-small-cell lung cancer.

The future holds much promise for our increased understanding of the structure and function of protein kinases and phosphatases. A combination of gene mutation studies, X-ray crystallography and

NMR structural structures are helping to reveal the molecular basis of enzymatic activity and substrate specificity. In conjunction with molecular modeling studies, this structural information can aid in the rational design of more potent and selective enzyme inhibitors. These compounds are helping to define further the role of particular kinases and phosphatases in signal transduction and in the evaluation of their suitability as targets for therapeutic intervention in disease. The next few years represent an exciting time in the field of protein phosphorylation in terms of seeing how understanding fundamental biology is enabling the development of new medicines for the treatment of human diseases.

Keywords

Solid-phase Oligonucleotide Synthesis
The primary technique used for chemical synthesis of oligonucleotides via sequential addition of monomers to a growing, resin-bound chain.

Phosphorothioate-containing DNA
A nuclease-resistant form of DNA in which one of the two unesterified phosphate oxygens is replaced with a sulfur atom.

Enzyme Inhibitors
Molecules that are able to prevent enzyme catalytic action.

Catalytic Antibodies
Antibodies that have been generated to catalyze specific chemical reactions.

Transition-state Analogs
Molecules that closely resemble the shape and charge of a reaction's transition state (more accurately known as the activated complex).

Combinatorial Chemistry
Method of synthesis of large numbers of molecules by the reaction of sets of monomer units at multiple positions.

Bioorganic chemistry is the study of biological systems, utilizing the tools of the organic chemist, usually including a synthetic component.

1 Introduction

Bioorganic chemistry is the study of biological systems utilizing the tools of the organic chemist, usually including a synthetic component. Bioorganic chemists pursue a wide range of activities including the study of biomechanisms, enzyme models, biosynthesis, biomimetic synthesis, molecular recognition, enzymology, peptide chemistry, nucleic acid chemistry, immunology, and the design and synthesis of therapeutic agents. Within the past decade, the classical distinctions among scientific disciplines have gradually faded so that frequently one finds the synthetic organic chemist making compounds of biological interest and, conversely, the biochemist using synthetic techniques to aid in answering biological questions. In this article, we discuss some highlights of bioorganic chemistry ranging from the more organic to the more biochemical. Areas of greatest interest to molecular biologists are emphasized.

Before delving into specific topics that relate bioorganic chemistry to molecular biology, we will explore in a more general way the physical and chemical principles that govern these topics and, indeed, govern all systems that one can observe in

nature. An understanding of these principles will allow a deeper understanding of all of biochemistry. The principles will be divided into two subareas: covalent and noncovalent. The covalent section will explore some of the fundamental organic reactions that one sees in much of biochemistry. The noncovalent section will examine the forces that govern the association of molecules.

2
General Principles

2.1
Covalent

There are literally hundreds of specific chemical reactions that are found in biological systems, and a study of the breadth of these is obviously outside the scope of this review. This huge number of reactions can be ordered by a variety of reaction types. One of the most prevalently observed reactions in biochemistry is hydrolysis and its reverse reaction, which is considered a type of condensation. These two general classes of reaction account for such processes as DNA/RNA polymerization and degradation, protein synthesis and degradation, muscle action, regulation via phosphorylation, and so on. Despite the variety of the reactants and products in these examples, they all have features that make them chemically similar.

To define terms, let us examine the hydrolysis of ethyl acetate, which is the ethanolic ester of acetic acid (Fig. 1). In the reaction, the electropositive carbonyl carbon is attacked by a water molecule. A tetrahedral intermediate is formed that can either revert to the starting materials or form products, that is, acetic acid and ethanol. In this reaction, ethanol is the leaving group and water is the attacking group or nucleophile. The reverse reaction, in which ethanol and acetic acid form ethyl acetate, is called a *condensation* because in the process of reaction, a molecule of water is released.

Ethyl acetate is an ester, a subclass of the compounds known as acyl derivatives, that is, compounds that are formed when carboxylic acids condense with another species. Figure 2 shows some of the variety of acyl derivatives found in nature and in the laboratory. The amide is the condensation product of an amine with a carboxylic acid, in the same way that an ester is the condensation product of an alcohol with a carboxylic acid. The thioester is the product of condensation of the thioether coenzyme A with butyric acid. Acetyl chloride is the condensation product of acetic acid and hydrochloric acid. As with the ester ethyl acetate, each of these compounds can undergo hydrolysis to form the free acid and another product. The ease with which this reaction can occur depends crucially on the species that has condensed with the carboxylic acid. For example, in aqueous solution at pH 7, it will take weeks for an amide to show signs of decomposition by hydrolysis, whereas an acid chloride will

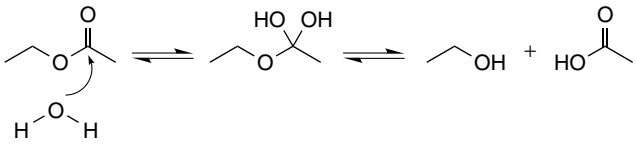

Fig. 1 Hydrolysis of ethyl acetate.

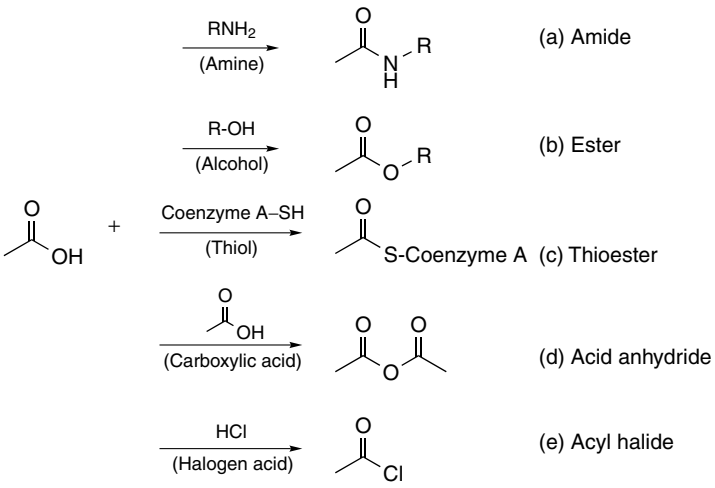

Fig. 2 Acyl derivative ranked from greatest hydrolytic stability (highest) to lowest hydrolytic stability (lowest).

be quantitatively hydrolyzed in a matter of minutes. This ease of hydrolysis, or stability, of the compound has profound biochemical ramifications.

It is fairly straightforward to estimate the relative stability of acyl derivatives. This stability is roughly proportional to the pK_a of the conjugate acid of the group attached to the carbonyl carbon (the group that will be replaced by water); the stronger the conjugate acid, the less stable towards hydrolysis the acyl derivative will be. For example, in the case of the amide, the group attached is RNH. The conjugate acid of this is RNH_2 or simply an amine. The pK_a of this is very high, on the order of 38. (Note, this is the pK_a of the *amine*, not the pK_a of the corresponding ammonium ion.) On the other end of the scale, if we examine acetyl chloride, the group attached is Cl. The conjugate acid of this is HCl or hydrochloric acid. The pK_a of this is on the order of −7. The other acyl derivatives, esters, thioesters, and acid anhydrides, all having attached groups whose conjugate acid pK_a values are intermediate to these two extremes, are found to be of intermediate stability (Fig. 2).

What is the reason behind this relationship? One way of looking at it is as follows: if the pK_a of the conjugate acid of the attached group is high, it means that it is not very acidic. In other words, the acidic proton is bound tightly. This tight binding indicates that the attached group is capable of donating electrons to produce effective bond formation, which in turn reduces the amount of free proton in solution. When the attached group is attached to the carbonyl carbon instead, this effectiveness of bond formation is preserved and is manifested in the bond stability.

For example, consider acetic anhydride from Fig. 2. This is the condensation product of two molecules of acetic acid. It is an effective reagent for adding acetyl groups to nucleophiles, such as amines. The conjugate acid of the attached group would simply be acetic acid, which with a pK_a of 4.5 satisfies the criterion of being a good leaving group for the reasons stated above. When the amine attacks the

carbonyl carbon to form the tetrahedral intermediate, either the amine or the acetic acid can be expelled to form the starting materials. Most of the time, the acid will be expelled because it is less able to contribute its electrons to make an effective bond.

In the same way that carboxylic acids can condense with alcohols to produce esters, so can other acids such as phosphoric acid and sulfuric acid. In the biological realm, condensation products of phosphoric acid are of greatest interest. It is useful to think of the chemistry of phosphoric acid condensation products as analogous to carboxylic acid condensation products (Fig. 3). A major difference between the two is that phosphoric acid has three acidic OH groups whereas carboxylic acids have only one. The result of this is that phosphoric acid can form multiple condensations. The most important of these in the molecular biology realm is the phosphodiester linkage that forms part of the backbone of DNA. And as with carboxylic acids, phosphoric acids can also form anhydrides. In the same way that carboxylic acid anhydrides are effective acylating agents because of the quality of the leaving group, phosphoric acid anhydrides are effective phosphorylating agents. The most well-known biologically important phosphorylating agents are the nucleotide triphosphates such as adenosine 5′-triphosphate (ATP).

The formation of the phosphodiester linkage between two nucleotides during DNA biosynthesis demonstrates some of the similarities and differences between phosphorylation and acylation chemistry (Fig. 4). The nucleophile in this case is the 3′-hydroxyl of the elongating nucleotide strand. It attacks the alpha phosphate of the next nucleotide triphosphate, forming a pentacoordinate intermediate. (It is pentacoordinate because the phosphate initially has four groups attached.) The intermediate can then either revert to starting materials or proceed to the diester product by ejecting the pyrophosphate group (the two attached phosphates). As with the acylation of amines with acetic anhydride, the reaction proceeds toward products because of the superiority of the phosphate as a leaving group compared to the attacking alcohol. In this reaction, the pyrophosphate is the leaving group. Nucleotide triophosphates are frequently used in nature to

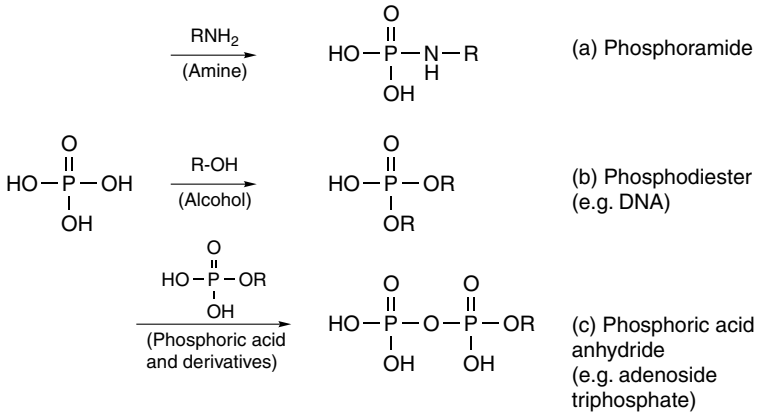

Fig. 3 Phosphoric acid condensation products.

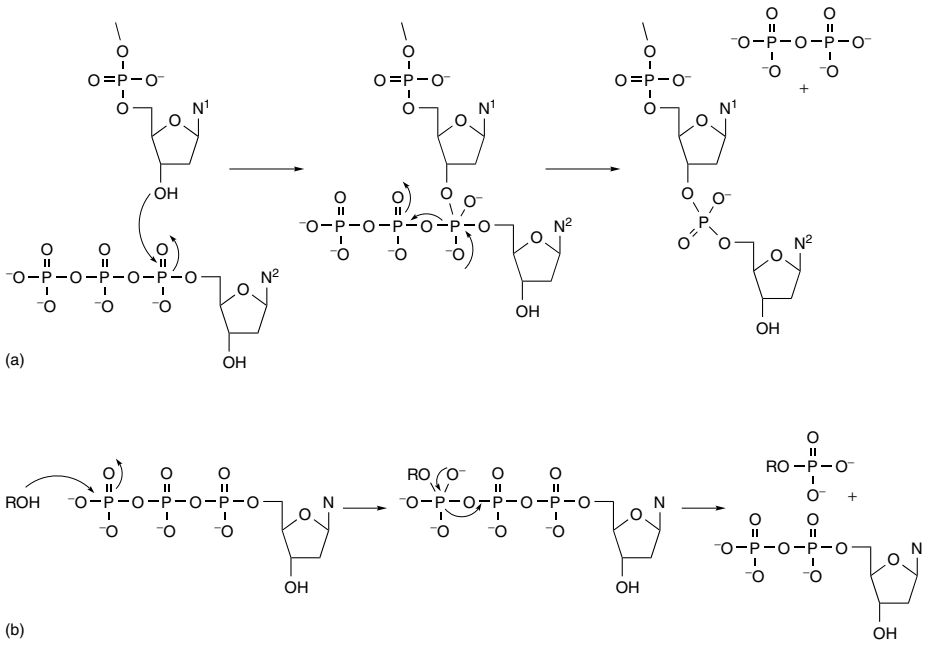

Fig. 4 (a) Polynucleotide biosynthesis. (b) Nucleophile phosphorylation with ATP.

transfer phosphate groups to nucleophiles like the hydroxyl groups of glucose during glucose metabolism. In this case, the nucleophile will add to the gamma or terminal phosphate, and the leaving group will be adenosine diphosphate, ADP, not pyrophosphate.

2.2 Noncovalent Interactions

We now turn our attention to the realm of noncovalent interactions, those forces that cause molecules to associate with and recognize each other. These interactions are of importance in all of biochemistry, from the specific hydrogen bonding patterns in the base pairs of DNA that allow for information to be coded to the enzymes' ability to distinguish between two ligands that can differ by a single methyl group. In addition to aiding in the understanding of binding processes, these forces are of key importance in the realm of catalysis as well. This concept will be explored at greater length later.

The hypothetical binding process of a protein "P" and a ligand "L," forming a complex PL can be described by a simple equilibrium (Fig. 5). The equilibrium association constant $K_a = [PL]/[P][L]$ is related to the standard free energy of binding (ΔG°_{bind}) through the expression $\Delta G^\circ_{bind} = -RT \ln K_a$ (where R is the universal gas constant and T is the temperature). This ΔG°_{bind} in turn is the sum of many factors such as coulombic attractions, hydrogen bonding, hydrophobic effects, van der Waals' forces, conformational effects, and translational/rotational entropy. A good rule of thumb is that for every 1.4 kcal mol^{-1} increase in ΔG°_{bind}, there is a tenfold increase in binding affinity. ΔG°_{bind} being a free energy, which

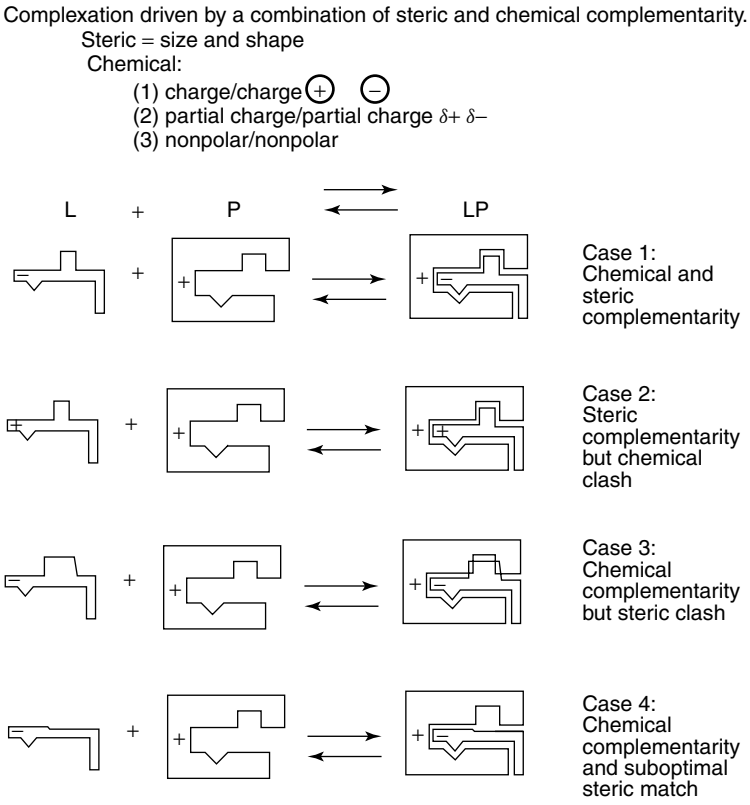

Fig. 5 Schematic representation of protein (P) ligand (L) association. Case 1 represents the optimal situation with simultaneous steric and chemical complementarity.

reflects the overall stability of the system, is a combination of two terms, enthalpy (ΔH°) and entropy (ΔS°) following the equation $\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ$. An overall negative $\Delta G^\circ_{\text{bind}}$ is indicative of a favorable process, so the trend is that reactions that have a decrease in enthalpy and an increase in entropy will tend to occur spontaneously, although either term can overcome the other. Enthalpy refers to the change in attractions and repulsions that occur during the reaction that are the result of forces (such as coulombic forces and intramolecular forces such as bond stretching.) The entropic term refers to the change in the ''randomness'' in the system or the number of configurations the system can adopt.

For the most efficient binding of the ligand, it should have both steric and chemical complementarity to the target site. Steric complementarity refers to the shape of the ligand versus the shape of the binding site. Chemical complementarity refers to the appropriate matching of surfaces on the ligand with the binding site. On average, surface elements that contact each other should have opposite charges on the ligand and the site to allow for effective

electrostatic interaction, or both should be nonpolar (uncharged) to allow for effective hydrophobic interaction (Fig. 5).

2.2.1 **Electrostatic**

Electrostatic interactions refer to charge–charge interactions. An example of this is the close contact of a positively charged amino group and a negatively charged carboxyl group (this arrangement is also known as a salt bridge). Coulomb's law describes the energy that is released when two charges are brought together (Fig. 6). From the form of the equation, we can see that the energy is directly proportional to the charges on the species and inversely proportional to the distance separating them. In addition, the dielectric constant indicates the ease with which the electrostatic field is propagated through the medium (a vacuum has a dielectric constant of 1, whereas the value for water is 79). Misuse of this equation can lead to bizarre conclusions. For example, if one calculates the energy released upon formation of a salt bridge using the distance of van der Waals' contact and the dielectric constant of a vacuum, the result is an energy on the order of 60 kcal mol^{-1}. In

$$\text{Electrostatic interaction energy} = \frac{(\text{Charge 1}) \times (\text{charge 2})}{\text{Distance} \times \text{dielectric constant}}$$

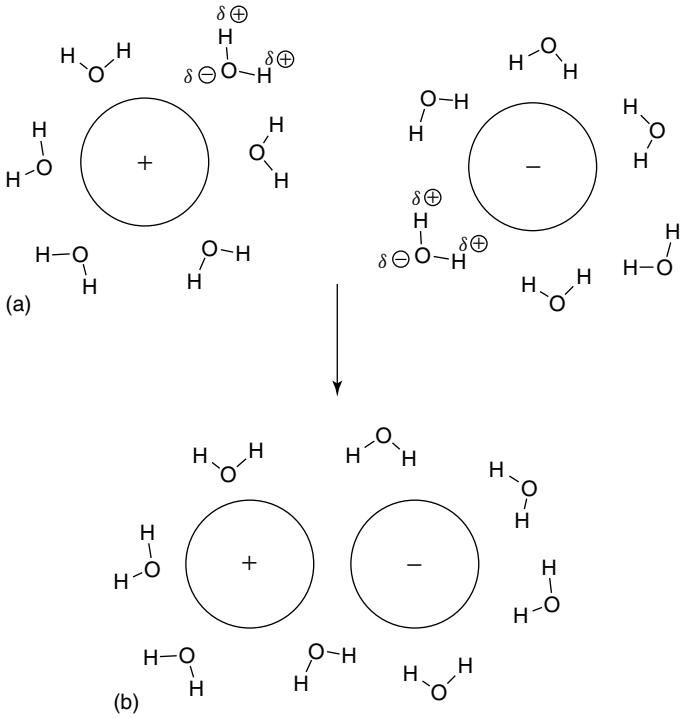

Fig. 6 (a) Electrostatic interaction energy. (b) Schematic representation of the salt bridge–forming process showing the desolvation of the charged species and its interaction with water dipoles.

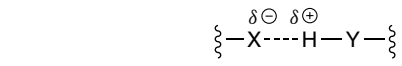
reality, the contribution of a salt bridge to the stability of a complex is on the order of 0 to 3 kcal mol^{-1}. The source of this difference lies in the presence of water. In all associative processes, it is imperative not only to examine the energy being released by bringing two groups together but also the energy required to remove the species from contact with the solvent (i.e. water). In the case of the salt bridge, this requires taking into account the desolvation of the amino group and carboxyl group as the salt bridge forms. This desolvation is an energetically expensive process because although water has no net charge, it still has a strong attraction to charged groups because of its dipole moment (i.e. separation of charge within the molecule) (Fig. 6). In addition to this effect, water decreases all electrostatic interactions through a general shielding effect.

An example of salt bridges in action may be found in the structure of the restriction endonuclease ECO RV bound to an oligomeric double-stranded DNA. Along the contact surface of the nuclease and the polynucleotide, there are seven positively charged groups (arginines, lysines, and histidines) within salt bridge–forming range of the anionic phosphate backbone of DNA, while no negatively charged groups (aspartic and glutamic acids) are in similar positions. These nonspecific salt bridges ensure that the nuclease will bind to DNA in general, while other specific hydrogen bonding interactions give it specificity for its unique cleavage site.

2.2.2 **Hydrogen Bonding**

Hydrogen bonding is also an electrostatic interaction, although the participants are not necessarily formally charged. Examples of hydrogen bonds are shown in Fig. 7. The defining characteristics are (1) a hydrogen atom attached to an electronegative atom such as nitrogen or oxygen (this is the hydrogen bond donor) and (2) a lone electron pair on a nitrogen or oxygen (this is the hydrogen bond acceptor). The hydrogen has a partial positive charge due to the electron-withdrawing nature of the atom to which it is attached, and this interacts with the negatively charged lone pair on the hydrogen bond acceptor in an essentially coulombic attraction. Hydrogen bonds also contribute on the order of 0 to 3 kcal mol^{-1} to molecular associations, although there can be variation in this number.



X and Y are electronegative atoms such as O and N

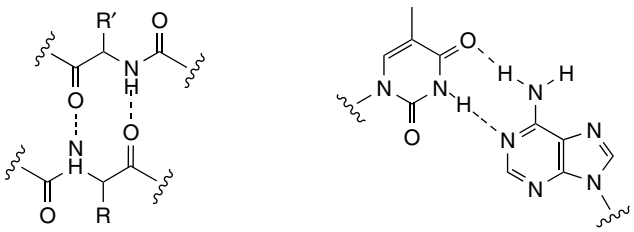


Fig. 7 Hydrogen bond formation in (left) protein beta sheets and (rights) nucleotide base pairing.

2.2.3 Hydrophobic Effect

The hydrophobic effect refers to the tendency of nonpolar species to associate in water and thereby limit the extent of their water contact. Macroscopically, this is manifested in the separation of oil from water. Microscopically, this is manifested by the tendency for side chains of nonpolar amino acids to cluster in the interior of proteins, away from water contact. In a variety of studies, it has been demonstrated that there is a linear dependence on the amount of nonpolar surface a molecule has and its tendency to prefer nonpolar environments. Although this is a complex and by no means a fully understood phenomenon, it appears to be entropically driven. A nonpolar surface cannot hydrogen bond effectively with water molecules. The result is that there is an ordering of water molecules around nonpolar species, with each water orienting so as to maximize the number of hydrogen bonds. The result is that these waters are limited in their range of motion, resulting in a decrease in entropy and therefore an (free) energetically unfavorable situation. The more nonpolar molecules cluster, the less (non–hydrogen bonding) surface they expose to water and the less of this water ordering takes place.

2.2.4 van der Waals' Interactions

In addition to the strong interactions of charges found in salt bridges and hydrogen bonds, there are weaker forces that allow principally uncharged species to also have attractive (and repulsive) interactions with other species. This is so because although these nonpolar species have no formal charge or dipole, they can transiently form a dipole due to random fluctuations of electrons within them. These transient dipoles can interact with other transient (and nontransient) species. In general, because of the random generation of these dipoles, van der Waals' forces are rather weak forces, acting over short distances. A classical example of van der Waals' attraction is between the stacked bases of DNA.

2.2.5 Conformational/Configurational Aspects

In addition to all of the specific attractive and repulsive forces described above, there are several other important factors that influence molecular associations. First of all, there is conformational free energy. If a molecule has to adopt a highly strained conformation in order to bind productively to its host, its affinity for the host will be decreased relative to a similar molecule that can make the same interactions without adopting the strained conformation. Furthermore, if a molecule can adopt many conformations (i.e. a so-called conformationally flexible molecule) and only a few of these can productively bind, then its affinity too will be decreased relative to a rigid, conformationally restricted molecule that can make similar interactions.

Finally, there is the rotational/translational entropy loss that accompanies binding. This is the free-energetic cost of preventing a molecule from moving freely in solution. This is a fixed cost in the sense that it will always have to be paid when two molecules associate. Before two molecules associate, they each have three rotational and three translational (movement through space) degrees of freedom, for a total of 12. These degrees of freedom are related to the system's entropy, the greater the number of degrees of freedom, the greater the randomness (and entropy). After the complex forms, there is essentially a single species having three degrees of rotational and three degrees of translational freedom. The overall entropy is decreased,

which is unfavorable from the standpoint of free energy. It is difficult to determine exactly the free-energetic cost of losing rotational/translational entropy upon complexation, but it has been estimated through a variety of techniques to be on the order of 7 to 11 kcal mol^{-1}.

3 Nucleotide Interactions

A wide variety of bioorganic investigations deal with molecules that interact with DNA. The purposes behind these investigations are manifold, ranging from the development of therapeutics to the understanding of the forces required for molecular recognition. The following section is divided into two parts. The first deals with synthetic oligonucleotides interacting with DNA, the second with small molecules that interact with DNA.

3.1 Oligonucleotides

The revolution in recombinant DNA technology relies critically upon the ability to synthesize a variety of oligonucleotides quickly and cheaply. The development of solid-phase oligonucleotide synthesis has made this process relatively simple. In addition to the many uses of these oligonucleotides in recombinant DNA manipulation (ranging from use as polymerase chain reaction (PCR) primers to the generation of site-directed mutants), they have potential as therapeutics in the field of antisense therapy, gene therapy, and RNA interference. Paralleling that use, in solid-phase peptide synthesis (SPPS), a common synthetic strategy that is used in oligonucleotide synthesis is depicted in Fig. 8.

There are many variations on this chemistry, not only for the production of natural DNA but also for the production of unnatural polynucleotides that have alternative backbone and nucleic acid structures. An example of the latter is phosphorothioate-containing DNA, in which one of the two unesterified phosphate oxygens is replaced with a sulfur. This may be achieved by replacing the hydrogen peroxide or iodine in the phosphite oxidation step shown in Fig. 8 with a solution of elemental sulfur. Phosphorothioate DNA has been found to have greater resistance to nucleases (enzymes that cleave the diester backbone of DNA), which makes it more suitable for antisense therapy than naturally occurring DNA.

Other approaches to artificial DNA have been tried that completely bypass the use of phosphate derivatives. Once again, the rationale behind this is to make a selective agent that will bind to a specific gene target but will be resistant to nucleases. P.E. Nielsen and coworkers have recently developed a group of DNA analogs in which the bases are connected to a poly*amide* backbone (Fig. 9). The result is an uncharged species that is capable of forming specific base-pairing hydrogen bonds with target genes. In addition to having resistance to nucleases, these peptide nucleic acids, or PNAs, form complexes with their target nucleic acid sequences that appear to be even tighter than those found in natural DNA duplexes. A probable cause of this phenomenon is the lack of negative charge on the PNA compared with the normal hybridization partner. We previously described the energetic advantage of coulombic attraction through, for example, the formation of salt bridges between negatively and positively charged species. The flip side to

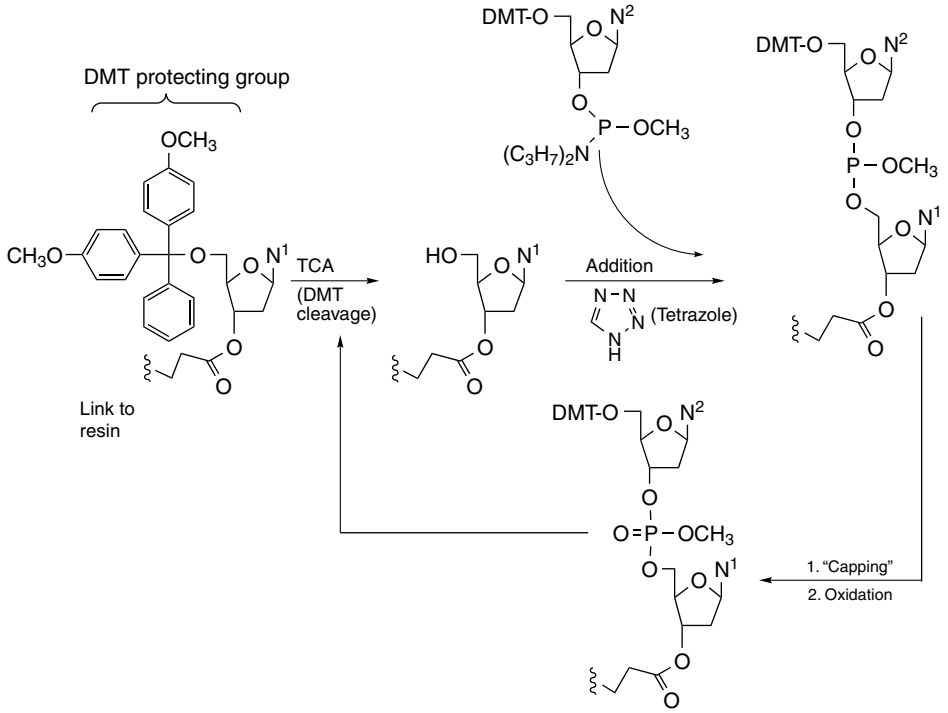

Fig. 8 Oligonucleotide synthesis begins with the tethering of the first monomer to an insoluble resin via an ester linkage to its 3′ hydroxyl group. To prevent esterification of the 5′ hydroxyl instead, it is blocked with a dimethoxy trityl group (DMT). After the ester linkage to resin has been formed, the DMT group is cleaved with acid. The next monomer (also 5′ hydroxyl DMT protected) contains a phosphoramidite group attached to its 3′ hydroxyl. The displacement of the phosphoramidite amine by the deprotected 5′ hydroxyl is catalyzed by the addition of tetrazole. ''Capping'' or acetylation of the 5′ hydroxyl group of any monomer that did not react with the phosphoramidite prevents errors from compounding. The capping prevents the unreacted, and therefore incorrect, oligomer from undergoing further chemistry. After the coupling between monomers has taken place, the phosphoramidite is oxidized to form the phosphate triester using either hydrogen peroxide or iodine. The DMT group is cleaved, thereby releasing the 5′ hydroxyl that can then participate in the next round of monomer addition. When the oligomer is complete, a final step of deprotection removes the final DMT group, any protecting groups on the nucleotide bases, and converts the phosphate triester into the naturally occurring diester.

this is that there is a destabilizing effect produced when like-charged species are brought together. This is precisely the situation with double-stranded DNA. The distance between phosphate groups on opposite strands can be as little as 8 Å, thus producing a significant electrostatic repulsion. Obviously, there are enough other interactions in dsDNA such as the hydrogen bonding between the base pairs and van der Waals' interactions between stacked base pairs to overcome this destabilizing influence. In the case of the PNA, these positive interactions are maintained, while the destabilizing electrostatic repulsion is eliminated. Thus, the stability of

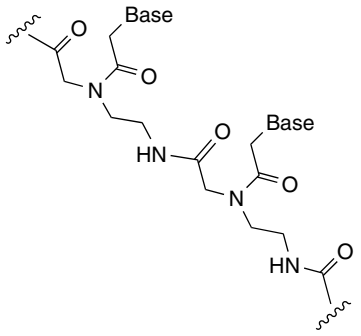

Fig. 9 PNA: peptide nucleic acid, a synthetic polynucleotide with an amide backbone.

the hybridized PNA is greater relative to its DNA analog.

In addition to alterations in the backbone, numerous bioorganic investigations have examined the effect of novel bases incorporated into DNA. (Many of these studies would be impossible without the prior development of efficient solid-phase oligonucleotide synthesis.) For example, Kool and coworkers have incorporated steric analogs of the nucleoside bases that have the same shape as the normal bases but have no hydrogen bonding capability. Difluorotoluene (Fig. 10) closely mimics the shape of thymine but is nonpolar and does not closely mimic its charge properties. Despite this, it can efficiently and specifically direct the incorporation of adenine opposite to it by DNA polymerase when it is used in oligonucleotides. This kind of result helps tease apart the relative importance of charge and shape in molecular recognition processes.

3.2 Small Molecules

There are literally hundreds of small molecules that have been found to have interesting or useful effects that depend upon their binding to DNA and form the basis for bioorganic investigations. The uses of these compounds include (1) antiviral and antineoplastic (anticancer) chemotherapies (e.g. bleomycin), (2) nucleotide stains (e.g. ethidium bromide), and (3) biochemical probes for nucleic acid structure (e.g. phenanthroline complexes). The major interaction modes are binding to the minor and major grooves, intercalation between stacked base pairs, as well as a host of potential

covalent modifications (including bond cleavage and alkylation) of the nucleotides, sugars, and phosphate backbone (Fig. 11). A well-studied DNA-binding small molecule is the natural product distamycin (Fig. 11), which has been shown to bind noncovalently and selectively to the minor groove of AT-rich portions of DNA.

In addition to having antiviral properties, which are probably linked to its ability to inhibit the enzyme DNA polymerase, distamycin has found use as a template for designing molecules with altered sequence specificity and sequence-specific cleavage.

The binding of distamycin to the minor groove of double-stranded DNA involves the combination of several of the previously described intermolecular forces. These include (1) conformational energy, (2) van der Waals' interactions, (3) hydrogen bonding, and (4) electrostatic interactions. The minor groove of DNA in the AT-rich regions to which distamycin binds is quite narrow, roughly the width of a single carbon atom. The distamycin molecule is composed of principally sp^2-hybridized (and approximately planer) atoms. Furthermore, uncomplexed distamycin exhibits a slight twist. This twist, brought about by subtle conformational forces within the molecule, is almost exactly the same as the twist observed in the spiraling minor groove of the double helix. Thus, there are none of the conformational energy penalties upon binding as described previously. Furthermore, because the groove width is very close to being the width of distamycin, there is an opportunity for extensive van der Waals' interactions between the faces of distamycin and the walls of the minor groove. Specific hydrogen bonds also play an important role in the binding. In the AT-rich regions of the minor groove to which distamycin binds, there are exclusively hydrogen bond *acceptors* in the form of lone pairs extending from nitrogens and oxygens of the exposed edge of the nucleotide bases. Distamycin in its natural conformation has exclusively hydrogen bond *donors*, in the form of amide protons, directed toward the floor of the minor groove. Finally, distamycin has a positively charged amidinium group at one of its ends. This contributes to the binding through electrostatic interaction with both the negatively charged phosphate backbone and the lone pairs on the minor groove floor.

The work of Dervan and others has extended the sequences that can be specifically targeted by minor groove–binding molecules such as distamycin. So-called hairpin polyamides that contain both the pyrrole rings of distamycin as well as the imidazole rings are able to bind to sequences of DNA by specifically recognizing and differentiating GC base pairs, CG base pairs, and AT/TA base pairs. The basis for this recognition is a side-by-side binding motif, where two planer oligomers (joined by a linker moiety) simultaneously bind to the minor groove (Fig. 12). It should be noted that this binding could not have been easily predicted from examining crystal structures of DNA, as the minor groove in most of these is far too narrow to accommodate two such molecules. DNA is a dynamic molecule and has been shown to be able to distort sufficiently to allow both molecules to bind. Binding specificity is rooted in the arrangement of pyrrole and imidazole rings. As noted above, the floor of the minor groove in AT regions of DNA is exclusively hydrogen bond accepting, exposing lone pairs of electrons with partial minus charges. Regions of the side-by-side hairpin polyamide that have a pyrrole across from a pyrrole bind to these AT regions, with hydrogen bonds being donated from the amide NHs that are adjacent to the pyrrole rings. Regions with GC or CG base pairs are recognized by an imidazole/pyrrole pair or pyrrole/imidazole pair respectively. This is because only G has the ability to donate a hydrogen bond (from an exocyclic NH) and only imidazole (with the lone pair on the unprotonated

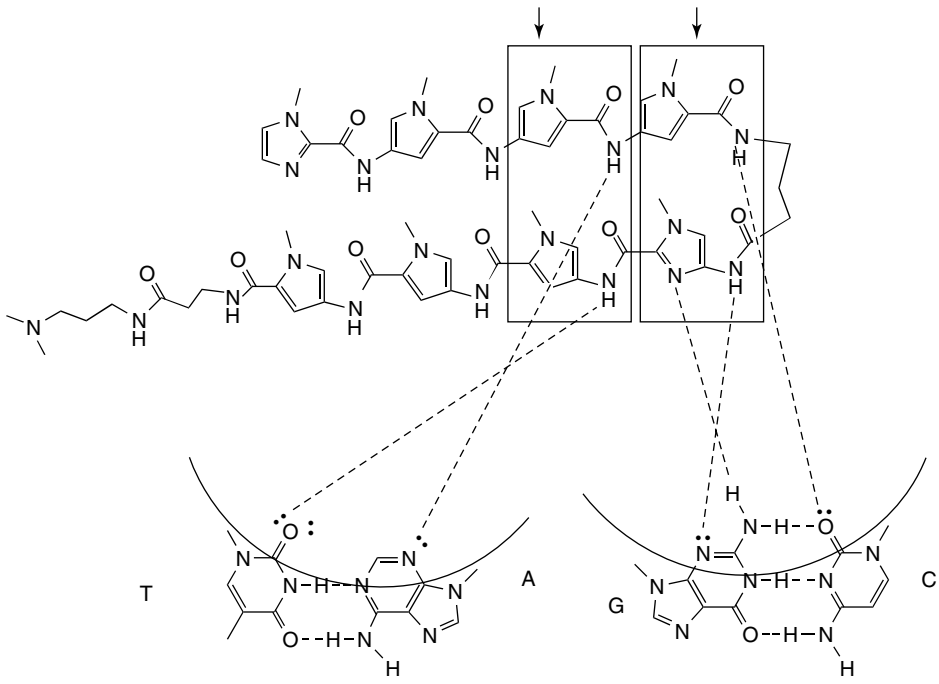

Fig. 12 Details of the mechanism of differentiation of AT and GC base pairs by "side-by-side" hairpin polyamides.

ring nitrogen) has the ability to accept a hydrogen bond. Oligomers built using these "pairing rules" of oligomer sequence matched with DNA sequence have shown remarkable affinity and specificity for sequences of DNA and may have application as in diagnostics and therapeutics.

4
Protein Studies

4.1
Enzyme Inhibition

The study of enzyme inhibition is a major focus of bioorganic chemistry for two major reasons. Firstly, enzyme inhibitors are useful tools for understanding enzyme structure and mechanism of action. Secondly, enzyme inhibition has proven to be a successful strategy for the design of therapeutics. Examples of drugs that act by inhibiting enzymes include methotrexate, Deprenyl, and Enalapril. Inhibitors can block enzyme function by preventing access of the natural substrate to the active site or by stopping the subsequent reaction from taking place by, for example, chemically blocking a key catalytic group on the enzyme.

There are two broad classes of inhibitors, covalent and noncovalent, the

distinction being whether or not a covalent chemical bond forms between enzyme and inhibitor. These classifications may be further divided into categories on the basis of kinetic and mechanistic criteria. Major subclasses include transition-state analogs, multisubstrate analogs, affinity labels, and mechanism-based inhibitors.

Noncovalent enzyme inhibitors rely on having two important features: (1) enough structural similarity to the actual enzyme's substrate to allow recognition and tight binding to the enzyme that is to be inhibited and (2) differences in the chemical structure that prevents the normal chemistry from taking place. An example of this type of compound is the drug Enalapril. It is the prodrug of Enalaprilat, which is an inhibitor of the protease angiotensin-converting enzyme (ACE). This enzyme cleaves the 10-residue peptide angiotensin I into the 8-residue peptide angiotensin II. These peptides are part of a pathway that controls blood pressure, and it has been found that preventing the conversion of angiotensin I to angiotensin II can be effective in reducing certain types of blood pressure (Fig. 13). This figure also shows schematically the interactions between enzyme and substrate that have been deduced to be crucial for binding affinity. Of note are a hydrogen bond to a carbonyl group, a salt bridge from the carboxyl terminus to a cationic site on the protein, and a putative hydrophobic pocket that binds the phenyl ring of the phenylalanine residue that is adjacent to the scissile (or cleavable) peptide bond. Also indicated schematically is an enzyme-bound zinc ion that is crucial for catalysis. It is shown to be interacting with the carbonyl of the peptide bond that is to be cleaved. It is believed that the zinc polarizes the carbonyl group, pulling electron density from the oxygen and therefore, indirectly, from the carbonyl

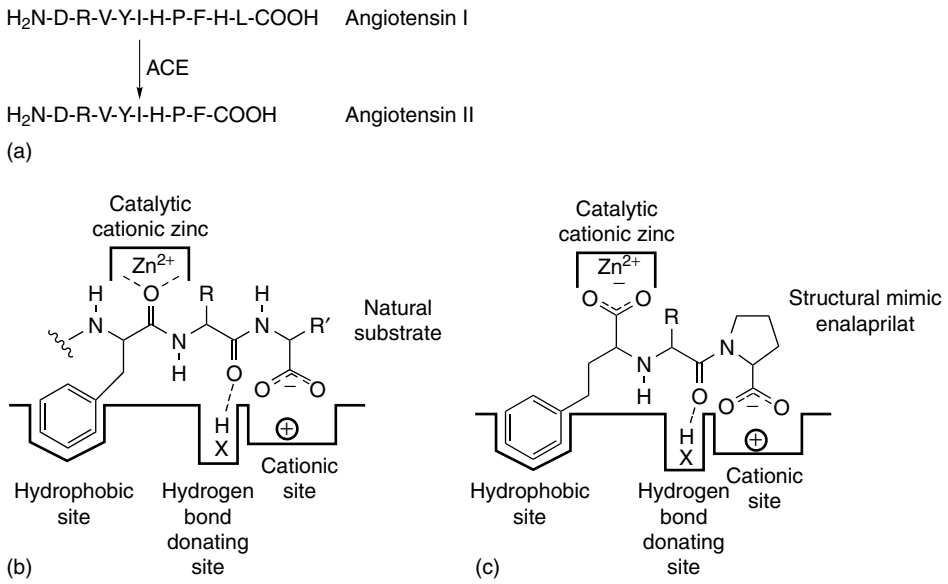

Fig. 13 (a) The reaction catalyzed by angiotensin-converting enzyme (ACE). (b) Schematic representation of the interaction of ACE with both substrate and (c) Enalaprilat, an inhibitor.

carbon. This makes the carbonyl carbon more susceptible to nucleophilic attack and reaction. Enalaprilat is able to make similar interactions with ACE. Figure 13 shows that the terminal salt bridge, phenyl ring, and carbonyl hydrogen bond are all maintained in positions similar to that of the natural substrate. A major difference is that the original scissile amide bond has been replaced with an unreactive amine. In order to maintain the interaction with the catalytic zinc, a carboxyl group is positioned in a similar orientation as the original carbonyl. This salt bridge is crucial for tight binding. Enalapril, the prodrug to this compound, is identical except that this carboxylate group is esterified, thereby making salt bridge formation impossible. It is also a far less potent inhibitor, evidently due to the lack of half of the salt bridge.

Covalent enzyme inhibitors also must have some structural similarity to the natural substrate in order to provide initial binding and specificity. An example of a covalent enzyme inhibitor is aspirin, or acetylsalicylic acid. It is a nonsteroidal anti-inflammatory agent. One of the ways by which it exerts this effect is by covalently modifying a critical amino group on the enzyme cyclooxygenase. Cyclooxygenase is an enzyme in the synthetic pathway of prostaglandins, which are key parts of the inflammatory response. The actual modification reaction is an acetylation.

4.2 Enzyme Catalysis

The previous paragraphs describe some of the fundamental organic chemistry found in biological systems. We now wish to demonstrate by example how some of these principles are applied in enzymes to achieve catalysis. One of the ways by which bioorganic chemistry examines this issue is through the design of small-molecule mimics of enzyme action. Enzymes are able to accelerate reactions in a variety of ways. One of these strategies, transition-state stabilization, will be discussed later. Another strategy is nucleophilic catalysis, where a reactive covalent bond is formed between enzyme and substrate that is then easily cleaved by another reactant. Frequently, enzymes take advantage of their ability to provide specific electrostatic interactions that can stabilize and promote the movements of charge within a molecule that will encourage its reaction.

For example, let us consider the reaction of ribonuclease A with its substrate, a single strand of RNA (Fig. 14). The reaction that is catalyzed is the cleavage of the phosphodiester bond to form a 3′-phosphorylated species and a 5′-free hydroxyl species. RNA is fairly stable at neutral pH, although the presence of the 2′-hydroxyl makes it less stable than DNA under similar conditions. The reason this is so is because the adjacent 2′-hydroxyl is a potential nucleophile that is in an ideal position to attack the phosphorus atom. Even though alcohols are not considered ''good'' nucleophiles, the proximity to the reactive center increases its reactivity. Ribonuclease A takes advantage of this adjacent nucleophile and improves upon its nucleophilicity by deprotonating it with the imidazole base of an active site histidine. In a sense, the partial minus charge on the unprotonated imidazole is transferred to the 2′-OH through the transfer of a proton. The anion is a better nucleophile (having greater negative charge, it will be attracted to the slightly positive phosphorus atom). The result of the 2′-OH attack is the formation of a pentacoordinate

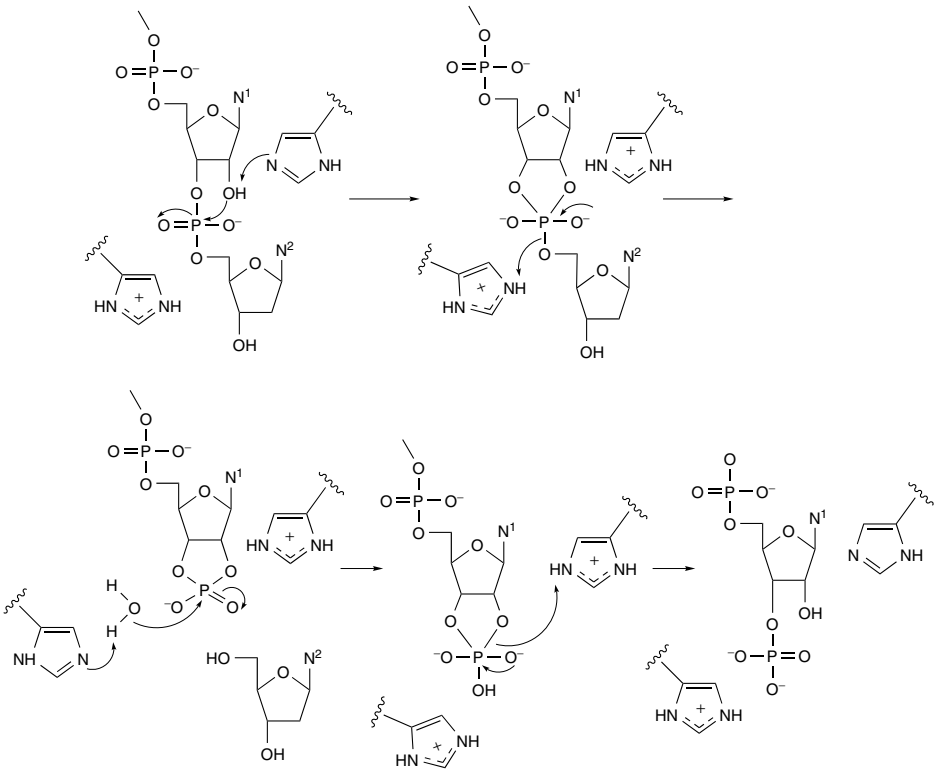

Fig. 14 The mechanism of catalysis of phosphodiester cleavage in single-stranded RNA by RNase A, accomplished by coordinated acid–base chemistry of two histidines.

intermediate. In essentially the reverse process, another active site histidine (which is protonated) protonates the 5′-OH of the other nucleotide. In doing so, it allows the flow of electrons in the phosphorus oxygen bond to migrate to the (now) positively charged 5′-OH–histidine complex. The result of this electron movement is the release of one of the products, the free 5′-OH nucleotide, and the formation of the cyclic phosphate form of the 3′-OH phosphate. In the same way that histidine A deprotonated the 2′-OH for attack originally, in the final step, histidine B deprotonates a water, essentially producing a nucleophilic hydroxide anion. This then attacks the cyclic phosphate intermediate. Histidine A can now act as an acid and protonate the 2′-OH. This again will allow the electrons in that P—O bond to migrate toward the positive charge. The result is the final product, the 3′-phosphate nucleotide. This reaction sequence demonstrates how the reactivity of specific groups can be significantly altered by specific electrostatic interactions. Furthermore, enzymes can both protonate and deprotonate virtually simultaneously, so that if the reaction calls for it, electrons can simultaneously be ''pushed'' and ''pulled.''

A rich area of bioorganic chemistry is in the development of small molecules that can in some way mimic the actions of

such enzymes by arranging key catalytic groups on an appropriate scaffold. A classic example of this is the development of small molecules that mimic the enzymatic action of ribonuclease (described above) by Breslow and coworkers. Using cyclodextran as a scaffold, they covalently attached two imidazole rings positioned to mimic the key catalytic side chains of the two histidines involved in catalysis by ribonuclease. This molecule showed activity in hydrolyzing a model phosphodiester in a manner analogous to ribonuclease (Fig. 15).

4.3 Transition-state Analogs and Catalytic Antibodies

Transition-state analogs are molecules that closely resemble a reaction's transition state (i.e. the highest energy species in the reaction pathway, more accurately known as an activated complex) in shape and charge. Enzymes are observed to bind tightly not to the substrates and the products of the reaction that they catalyze but rather to the transition state, the highest energy species that forms during

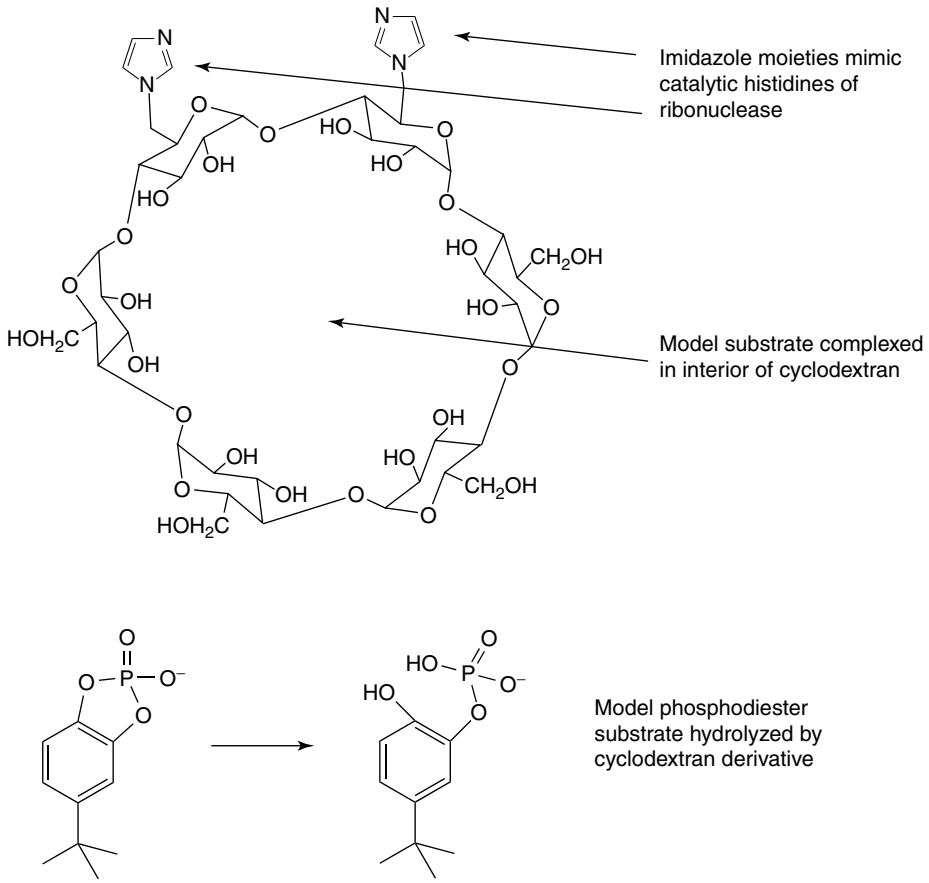

Fig. 15 Small-molecule mimic of RNase A, incorporating cyclodextran as a substrate binding site, and two imidazole moieties for catalyzing hydrolysis of the indicated model substrate.

the reaction. Enzymes have evolved to use this strategy for catalysis. By forming an active site that is complementary in shape and charge to the transition state, enzymes can stabilize or lower the energy of this species. The effect of this is to accelerate the reaction because the activation barrier is more easily overcome. This complementarity in charge and shape to the transition state is readily demonstrated by the effectiveness of transition-state analogs as enzyme inhibitors. A classic example of a transition-state analog is a phosphonate-containing molecule that mimics the transition state of the hydrolysis of the corresponding acyl derivative (Fig. 16). When an ester is hydrolyzed, the central carbonyl group changes from being planer (sp^2 hybridization of the carbonyl carbon) to being tetrahedral (sp^3 hybridization). The phosphonate-containing analog is able to reproduce the shape of the transition state as well as the partially negatively charged oxygens. In addition, it is chemically stable, whereas the actual transition state exists only fleetingly. In this example, an enzyme that catalyzed the hydrolysis of this ester would also bind tightly to the phosphonate analog. Transition-state analogs are a successful strategy for enzyme inhibition, one that forms the basis of several drugs.

In addition to generating effective enzyme inhibitors, transition-state analogs can be used to generate antibodies that are capable of catalyzing chemical reactions (so-called ''catalytic antibodies''). The theory underlying this approach is that antibodies that are elicited against a transition-state analog, and therefore have the ability to bind them, will be chemically and sterically complementary to the transition state and will therefore be potentially capable of catalyzing the reaction. The general strategy behind the production of a catalytic antibody is to (1) design and synthesize a molecule whose shape and charge closely resemble that of the transition state of the reaction one wishes to catalyze, (2) tether this molecule to a larger molecule, (3) elicit an immune response to this conjugate, and (4) screen the resultant monoclonal antibodies for

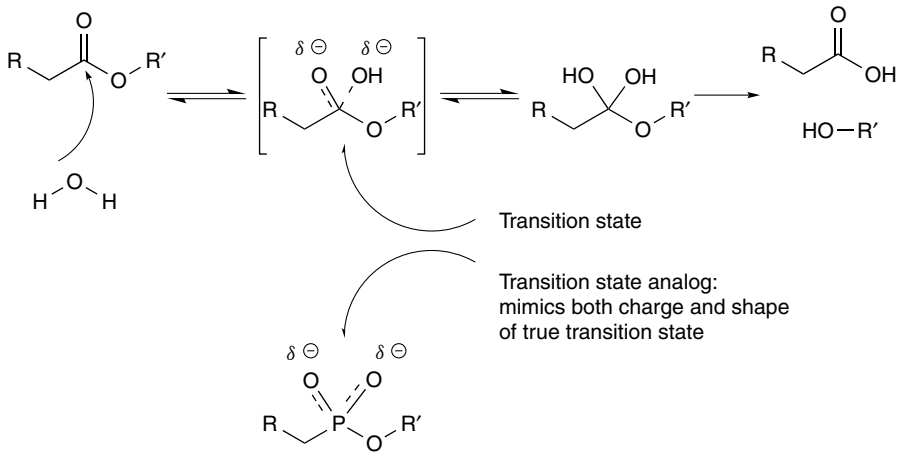

Fig. 16 Comparison of transition-state structure and transition-state analog structure for an ester hydrolysis.

catalytic activity of the type desired. This approach has proven successful in a range of systems.

4.4 Solid-phase Peptide Synthesis

Solid-phase peptide synthesis (SPPS) is a technique that allows the semi- or fully automatic synthesis of relatively long peptides without the need for purification of reaction intermediates. The basic strategy of SPPS is outlined in Fig. 17. The first amino acid of the peptide is tethered to a derivatized resin via its carboxyl group. The amino terminus of this first amino acid is freed from its protecting group by an appropriate cleaving system and then treated with the activated carboxyl of the next amino acid to be added to the chain. The amino group of this newly added amino acid is also protected to prevent condensation with the activated carboxyl. After the new peptide bond is formed, the new terminal amino group is deprotected and the cycle of condensation followed by deprotection can continue. In addition to protection of the alpha amino group of the newly added amino acid, the chemically reactive side chains of the peptide (such as the amino group of lysine and the carboxyl group of aspartic acid) are also protected with groups that will not be cleaved until after the peptide synthesis is complete. A major advantage of SPPS is that after each of these steps, the reaction by-products can be flushed from the container holding the resin. The peptide that is attached to the insoluble resin will remain in the container. The alternative to SPPS is solution-phase peptide synthesis, which, as with most organic synthesis, requires the isolation and purification of reaction intermediates, usually after each condensation reaction. Thus, making a peptide of even modest length becomes a major undertaking. In addition to removing a large amount of the purification from the process, SPPS lends itself very well to automation. A modern automatic solid-phase peptide synthesizer can make a peptide of 20 residues in length in about a day. The equivalent synthesis by solution methods would typically be on the order of months. Since each intermediate is not isolated and purified, the key to making SPPS a viable technique was the

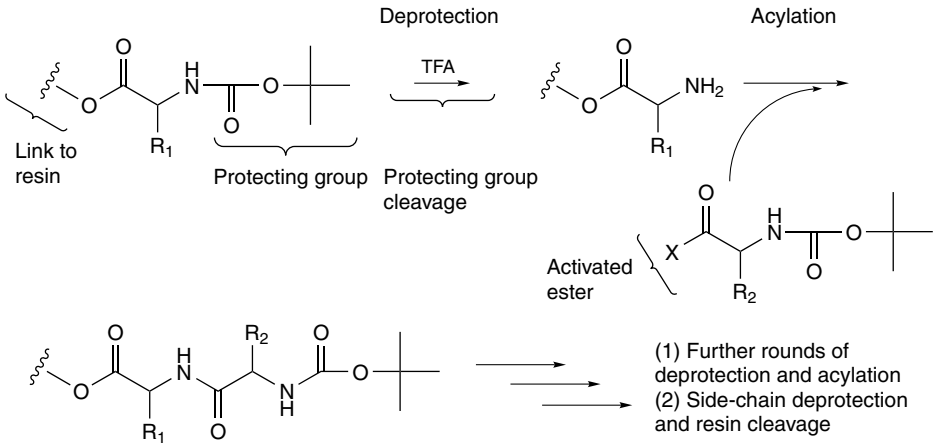

Fig. 17 Strategy of solid-phase peptide synthesis using BOC chemistry.

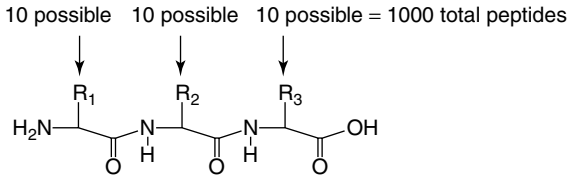
development of very efficient coupling reactions. If the coupling efficiency is 95%, a high yield under normal circumstances, in the process of making a 20-mer, 0.95^{20} or 36% of the resultant peptide will be of the sequence specified. The remainder will be a mixture of similar but incorrect peptides. Modern solid-phase peptide synthesizers are able to attain efficiencies on the order of 99%, which allows good purities to be attained.

5 Combinatorial Chemistry

A central area of bioorganic chemistry is the identification of small-molecule ligands for macromolecules. Such molecules can be used as biochemical probes as well as potential lead therapeutics. There are several paths that can lead to high-affinity ligands for macromolecules. Molecules that mimic the structures of known substrates can act as lead compounds. Three-dimensional structures of macromolecules determined by X-ray or NMR can be used as a guide to ''rationally'' design molecules that bind to identified binding sites. If efficient screening methods exist, large collections of compounds can be individually tested until a ''hit'' is found, which can then be optimized through the synthesis of derivatives. An additional method, that of combinatorial chemistry, has proven itself to be useful for identifying ligands for a range of systems. It has been made possible by the revolution of solid-phase organic synthesis, which allows the rapid synthesis of collections of molecules containing arbitrarily large numbers of species.

An example of this is shown in Fig. 18. It depicts the synthesis of a simple tripeptide library using 10 standard L amino acids. The peptide is constructed on an insoluble resin in a stepwise fashion. If each position during the synthesis is allowed to vary and be any one of 10 amino acids (we will discuss how this is done shortly), there will be a mixture of $10 \times 10 \times 10 = 1000$ possible tripeptides present at the end of the synthesis. The challenge then is to determine which, if any, of the members of this library bind to the target of interest. There are many approaches to this process, known as *deconvolution* of a library. Two of the most widely used approaches have been positional scanning and iterative deconvolution. In both these approaches, mixtures of compounds (sublibraries of the larger library) are tested and the results are used to identify an individual hit or hits.

In the process of positional scanning, sublibraries are constructed by using a specific amino acid at one given position and mixtures of amino acids at the remaining positions (Fig. 18). This is done multiple times, moving the specific amino acid along the length of the peptide. Therefore, at the end of the process for the tripeptide library described above, one will have three collections, each of which contain 10 sublibraries. As shown in the figure, each of the 10 sublibraries contains a mixture of products. This is a mixture of peptides that have a random amino acid at two positions and a specific amino acid at the remaining position. When all of these sublibraries are assayed, if there is a single ''winner'' to be found in the total library (for the purpose of argument Gly-Pro-Asp), then the subelements that contain that sequence in high concentration will show activity. The sequence of the ''hit'' can therefore be read directly from the activity results. It can then be resynthesized as an individual species and confirmed as an active molecule. In practice, there can



Positional scanning deconvolution:
30 sublibraries synthesized simultaneously:

R1-N-N	N-R2-N	N-N-R3	
N = random mixture of 10 amino acids	N = random mixture of 10 amino acids	N = random mixture of 10 amino acids	
R1 =	R2 =	R3 =

LYS	LYS	LYS	
GLN	GLN	GLN	
ARG	ARG	ARG	
ASP	ASP	[ASP]	

Fig. 18 Deconvolution of a three-position peptide library using the positional scanning approach.

be more than one clear winner at each position in the oligomer. If this is the case, then multiple resyntheses are warranted. For example, if there are two active sublibraries at the first position, two at the second, and three at the third, then $2 \times 2 \times 3$ or 12 new individual molecules should be synthesized as individual species to assess for activity.

A second approach for deconvolution is the method of iterative deconvolution (Fig. 19). This also uses the technique of having multiple random positions and individual fixed positions to identify individual active species from large libraries. Whereas positional scanning allows one to simultaneously synthesize and assay all sublibraries at once, iterative deconvolution requires a series of alternating synthesis and assay steps. Using the example of the tripeptide library above, deconvolution would begin by making a collection of 10 sublibraries in which the first position is fixed and the second two positions have random amino acids. Therefore, one would have a sublibrary of 10 elements. Each of these 10 elements would be assayed and the most active element would identify the specific amino acid at that position. A new collection of

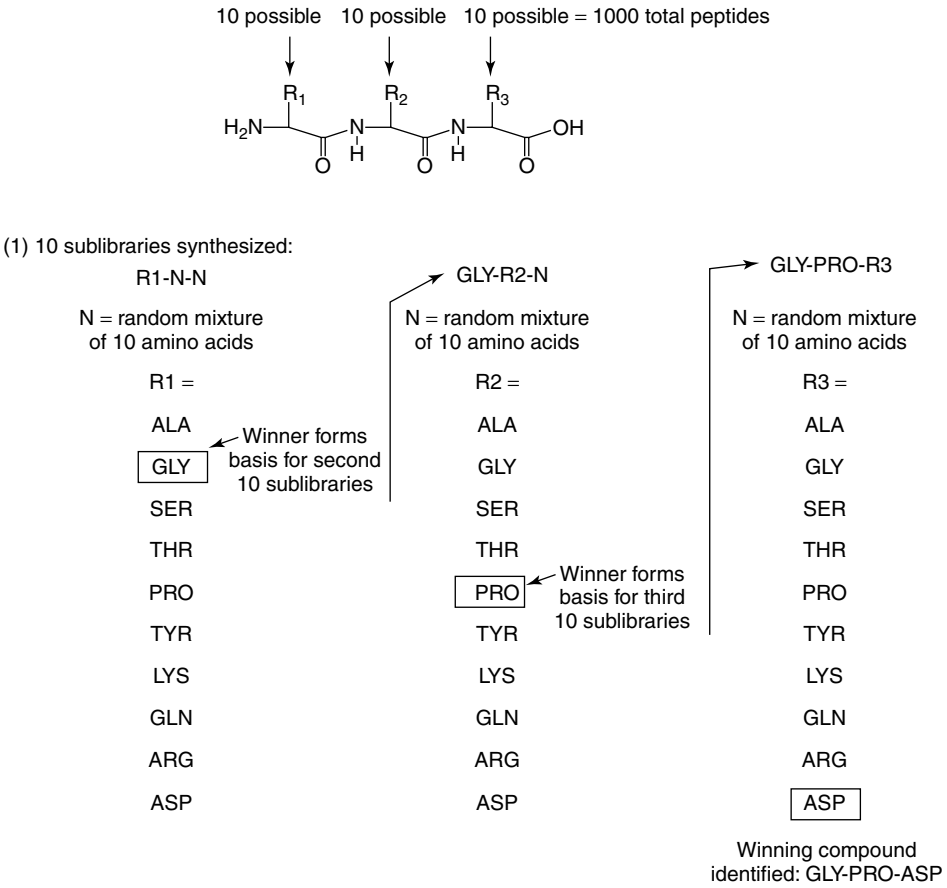

Fig. 19 Deconvolution of the same library from Fig. 18 using the method of iterative deconvolution.

10 sublibraries would then be synthesized, with the specific selected amino acid from the first round in the first position, 1 of the 10 possible amino acids in the second position, and a random amino acid selected from the third position. (See Fig. 19). This process would continue until a single high-activity species was identified from the final sublibrary.

Both these methods have been extensively used to determine the sequence of active species from large combinatorially generated mixtures. There is a range of other deconvolution strategies that have been described and contrasted. Both iterative deconvolution and positional scanning require that some positions in a sequence be randomized. There are two possible ways of doing this randomization. The most conceptually straightforward approach is to simply use a mixture of amino acids when coupling to a given position. One of the disadvantages of this method is that each amino acid in a mixture will have a different coupling rate and efficiency, which depends not only on itself but on the amino acid it is coupling to. The result of this is that some amino acids, if they are particularly reactive, can be overrepresented at the position. A way to avoid

this situation is to use a 1 : 1 ratio of incoming amino acid to resin-bound amine. This then requires longer coupling times to allow the slowest amino acids an opportunity to react. Some of the advantages of solid-phase synthesis are thus lost, as a large excess cannot be employed to drive the reaction.

An alternative to the use of mixtures of amino acids during coupling is the use of so-called split and mix synthesis. This method will work *only* with the method of iterative deconvolution. Using an example of a dipeptide library with three possible amino acids, a typical split and mix synthesis would begin by separating the resin to be used into three equal portions (Fig. 20). To each of these portions, a single specific amino acid would be attached (in the example these are G, P, and T). Because an individual amino acid is being used, it can be used in excess to drive the reaction to completion. (This is not possible when using a mixture of amino acids, without running the risk of more reactive amino acids overpopulating the product mixture.) When these reactions are complete, these three separate portions of resin are combined and mixed thoroughly, and again separated into three separate portions. Again, to each of these portions, a single specific amino acid is attached. These three portions are then again mixed thoroughly and separated into random mixtures. The resultant beads have fully random amino acids at each position and can then be specifically modified with a specific amino acid for use in an iterative deconvolution strategy. The difference between this approach and that of using mixtures of amino acids is the manner in which the random positions were generated. In the case of split and mix synthesis, the random positions are generated by using individual amino acids reacting with, and *then* mixing the resultant beads. The method of amino acid mixtures generates random positions by using mixtures of amino acids reacting at each position.

Both these methods for generating random positions can be effective and have strengths and weaknesses. Split and mix synthesis allows one to avoid the differential reactivity problem that can exist with random mixtures by allowing large excesses to react. Random mixtures on the other hand are easier to manipulate. In addition, for logistical reasons, only they can

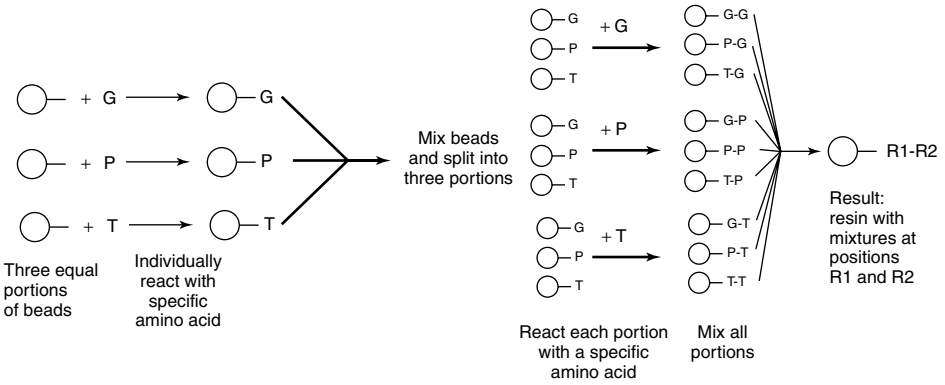

Fig. 20 Using the split and mix approach to generate resin with a bound mixture of all possible dipeptides using the amino acids G, P, and T.

be used to generate randomized positions in positional scanning libraries. (This is because in positional scanning libraries, there are random positions that occur *after* the specific defined positions.) Splitting and mixing would therefore lose the information contained in the defined position. In iterative deconvolution, however, the terminal position is always the defined position, so this issue is not relevant.

6 Molecular Modeling

A very useful tool in the study of bioorganic chemistry is molecular modeling, the simulation of molecules and their interactions. This single designation covers a vast region of study including methods of molecular mechanics, a range of approaches for conformational sampling, semiempirical methods, *ab initio* methods as well as the analysis of complex interactions (which may include all of the previously named techniques). The overall aim of these methods is to simulate properties of molecules, from the small scale (e.g. dipole moments) to the larger scale (e.g. thermal stability of a protein). All of these tools have limitations and, by definition, approximate the behavior of physical systems. At the minimum, it is suggested that a given computational technique be validated with a related system for which experimental evidence can be used to support the technique's application. If no such external validation is available, then the results of a simulation should be used cautiously.

Molecular mechanics is the computationally least-intensive method of estimating the energy of a molecule and the dependency of this energy on conformation. The basis of molecular mechanics is the *force field*, a mathematical representation of a molecule's energy based on an arithmetic sum of different terms. These terms assess the contributions made by bond stretching, bond angles, dihedral rotations, and other movements to the overall energy of the molecule. Figure 21 shows the equation for the AMBER force field. Because the forces that control these movements are simulated using very simple physical models (a stretching spring to represent a stretching bond, for example) the overall energy can be calculated very rapidly. The challenge is *parameterization,* the determination of the factors

$$\text{Energy} = \sum K_r (r - r_{eq})^2 + \sum K_\theta (\theta - \theta_{eq})^2 + \sum (V_n/2)[(1 + \cos(n\varnothing - \gamma)] + \sum (A_{ij}/R_{ij}^{12} - B_{ij}/R_{ij}^{6}) + \sum q_i q_j / eR_{ij}$$

Bond stretching | Bond angle | Bond dihedral angle | Van der Waal interactions | Electrostatic interactions

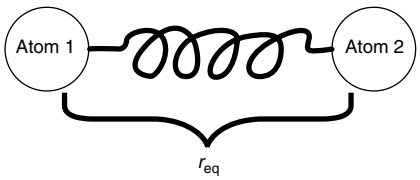

Fig. 21 Sample force field (AMBER). Simple physical model of energy dependence on atomic position: for example, bond stretching modeled as a spring stretch with energy required to displace atoms beyond their equilibrium separation.

that determine the changes in energy due to deviation from the ideal bond length, angle, and so on. The parameters of a force field are determined in multiple ways, including experimental techniques (e.g. ideal bond lengths from crystal structures, bond stretch force constants from spectroscopy) and high-level quantum mechanical calculations where no experimental values are available. There are many force fields available, including MMFF94, CHARM, AMBER, OPLS, MM2/MM3. Each is constructed and parameterized using different approaches and therefore each gives different results for different systems. Again, before overinterpreting the results given by a force field in analyzing a new system, it is important to assess the accuracy of the given force field in predicting experimentally known values in a related system.

Once a molecule is ''drawn up'' using a modeling package such as Sybyl, Spartan, or Hyper-Chem, it may have nonoptimal bond angles, distances, and so on. Energy minimization can then be used to ''relax'' the molecule into a local energy minimum. Energy minimization takes a multidimensional derivative of the energy with respect to a given atomic motion and determines the forces on a given atom. These forces sum to push the atoms into their local lowest energy position. This is a local and not a global energy minimum, because it is the nature of energy minimization that the molecule is always going ''down-hill'' energetically, and therefore it will be unable to traverse energetic barriers that may allow access to a lower energy conformation.

Why would a bioorganic chemist use molecular modeling? Often, it will be to understand what a molecule looks like, to determine, for example, how it may interact with a target macromolecule. For this purpose, it is of greater use to identify the global energy minimum structure, that is, the conformation of the molecule that will have the greatest population. This problem can be approached using a variety of tools, including systematic conformational searching (SCS), Monte Carlo searching, and molecular dynamics. Since a majority of the movement in a molecule is due to rotations around bonds, SCS looks for the global energy minimum by generating all possible conformers by incrementally advancing the dihedral angles of the molecule. This approach will definitely explore all possible conformations (within the resolution of the dihedral angle increment), but the number of conformations necessary to examine increases exponentially with each additional rotatable bond. Eventually, this can become computationally unwieldy.

To address this problem, Monte Carlo searches also rotate bonds in an attempt to traverse high-energy barriers but do so in a random manner that is biased away from conformers that are too high in energy. There is a trade-off at play here: The Monte Carlo search will not be as thorough as a systematic search (except at the highest number of cycles) but will avoid the very highest energy regions of confomer space, which the SCS will be forced to examine.

An additional method of searching for the global energy minimum of a molecule is simulated annealing, a tool of molecular dynamics. In molecular dynamics, the same force field used to model the static energy of a given configuration of atoms is used to determine its dynamic nature. Momentum is imparted to each atom (the amount being dependent on the ''temperature'' at which the dynamic simulation is run) and the resulting motions of atoms simulated using the force field. In simulated annealing, a high temperature is simulated (i.e. a large amount of momentum applied to the

atoms in the molecule), which results in portions of the molecule traversing energy barriers that could not normally be traversed. The result of this is that the conformations of the molecule are explored. ''Cooling'' of the molecule in the simulation then allows the molecule to settle into a local energy minimum. With enough rounds of heating and cooling, it is then possible to find the global energy minimum.

Molecular mechanics is an effective tool for predicting conformational energy; however, it cannot describe the electronic nature of a molecule, such as the energy of a transition state associated with the breaking of a bond, or overall reaction energies. For this and other applications where a detailed understanding of the electronic nature of a molecule is needed, quantum mechanical methods are required. The list of approaches is vast, including semiempirical methods (e.g. AM1, PM3), Hartree Fock methods, and correlated methods including Moeller–Plesset and density functional methods. The common element in all of these approaches is that they estimate solutions to the Schrödinger equation. As such, they are able to address questions involving movement of electrons (such as reaction energy), which molecular mechanics is unable to. This fundamental assessment of electron movement and energy in a molecule comes at a cost, which is the increased computational resources demanded of these methods.

A common aim in bioorganic chemistry is the design of small molecules to target macromolecules. Modeling of the structure of the small molecule can be performed using the techniques described above. Of further interest is modeling the potential for interaction of the small molecule with the target of interest. This examination can be done ''by hand'' in a qualitative fashion using interactive molecular graphics (e.g. programs such as MIDAS, Chimera, Rasmol). In addition, a range of docking programs exists that allows for rapid generation of potential complexes and their assessment via scoring functions. The algorithms used by these programs are fast enough that databases of $>100{,}000$ compounds can be virtually screened for potential interaction with a target macromolecule in a reasonable amount of time ($\sim \leq 1$ week). Docking programs include Dock, Autodock, and FlexX.

The methods described above for modeling a molecule's structure (molecular mechanics, semiempirical, and *ab initio* methods) are in general *in vacuo* methods. In other words, the result is a predicted structure or energy based on the molecule and its conformations while completely desolvated. For some molecules, in fact for most molecules that are of interest to bioorganic chemistry, this eliminates a very important factor from the calculation – the effect of solvent water. The presence of water diminishes electrostatic interactions by screening full and positive charges. In addition, it strengthens nonpolar–nonpolar interactions through the hydrophobic effect. For a true and accurate simulation of molecules in an aqueous environment, solvation energy corrections have to be applied. There are multiple approaches to doing this. One is to incorporate a shell of explicit water molecules in the simulation. This can be computationally very demanding. More efficient methods include so-called continuum methods, which do not include individual water molecules but model the solvent as a continuum. These include the SM (Solvation Model) methods of Cramer and Truhlar.

7 Summary

We have briefly attempted to highlight the principles of bioorganic chemistry that are of general importance and of special interest to the molecular biologist. In addition, we have sought to illustrate these with specific examples. Bioorganic chemistry makes connections with a very broad range of fields, ranging from physical chemistry to biochemistry. Obviously, we have just scratched the surface of these topics in this vital and rapidly expanding discipline.

Keywords

Bioprocessing
The engineering component of the commercial exploitation of biological materials, living organisms, and their activities.

Enzyme
High molecular weight proteins that lower the activation energy of a specific reaction resulting in faster reaction rates.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Edited by Robert A. Meyers.

ISBN: 3-527-30544-0

Genomics
A set of experimental and computational tools that allow genetic information to be read and related to the structure and function of an organism.

Hybridoma
A cell line produced by fusing a myeloma (cancer) cell with a lymphocyte; used to produce antibodies.

Recombinant DNA
A general term for laboratory manipulation in which DNA molecules or fragments from various sources are severed, combined enzymatically, and reinserted into host organisms to make a protein product.

Transgenic
A term describing an animal or a plant created by introducing new DNA sequences into the germ line via addition to the egg or the seed.

Bioprocessing is the engineering component of the commercial exploitation of biological materials, living organisms, and their activities. It is a diverse field requiring the collaboration of scientists, physicians, and engineers working in the areas of agriculture, biology, biochemistry, chemical engineering, electrical engineering, environmental engineering, genetics, material science, medicine, water, and wastewater treatment. Current biotechnology products include pharmaceuticals, fine chemicals, agricultural and food products, and biomaterials. In addition, bioprocessing is being evaluated for the production of nano-bio products, bioelectronics, and commodity chemicals. The use of more biologically based products is growing; global genomic initiatives and miniaturization assure industrial biotechnological growth. The desire to move toward more ''green factories'' that generate less environmental waste also contributes to industrial expansion. The current biotechnology industry is estimated to generate between $35 and $50 billion in sales and continues to be self-sustaining in terms of research and development.

1 Introduction

The roots of bioprocess engineering are in the food, tobacco, tea, leather, and other ancient industries. Of particular interest are the industries that use fermentation, not only in beer brewing and wine making but also in the production of antibiotics, citric acid, various amino acids, and other biomolecules. The art of yeast and bacterial fermentation is therefore well established. Throughout the 1990s, cell culture technology grew significantly as growth hormones, interferons, monoclonal antibodies, and artificial tissue

products entered clinical trials. Current frontiers include stem cell research for tissue, organ, and bone replacements; integrated fermentation and downstream process development; and production of protein from transgenic plants and animals.
